ABSTRACT

We report on *Chandra* and *XMM-Newton* observations of a sample of 13 quasars at $z \approx 4.7$–5.4 mostly taken from the Sloan Digital Sky Survey (SDSS). The present sample complements previous X-ray studies of $z \geq 4$ quasars, in which the majority of the objects are optically more luminous and at lower redshifts. All but two of our quasars have been detected in the X-ray band, thus doubling the number of $z \geq 4.8$ X-ray–detected quasars. The two nondetections are likely to be due to a short exposure time (SDSSp J033829.31+002156.3) and to the presence of intrinsic absorption (SDSSp J173744.87+582829.5). We confirm and extend to the highest redshifts the presence of a correlation between $AB_{1450(1+z)}$ magnitude and soft X-ray flux for $z \geq 4$ quasars and the presence of a steeper optical–to–X-ray spectral energy distribution (parameterized by α_{ox}) for high-luminosity, high-redshift quasars than for lower luminosity, lower redshift quasars. The second effect is likely due to the known anticorrelation between α_{ox} and rest-frame 2500 Å luminosity, whose significance is confirmed via partial correlation analysis. The joint $\approx$2.5–36 keV rest-frame spectrum of the $z > 4.8$ SDSS quasars observed thus far by *Chandra* is well parameterized by a power law with photon index $\Gamma = 1.84^{+0.31}_{-0.30}$; this photon index is consistent with those of $z \approx 0$–3 quasars and that obtained from joint spectral fitting of $z \approx 4.1$–4.5 optically luminous Palomar Digital Sky Survey quasars. No evidence for widespread intrinsic X-ray absorption has been found ($N_H \lesssim 4.0 \times 10^{22}$ cm^{-2} on average at 90% confidence). We also obtained Hobby-Eberly Telescope (HET) photometric observations for eight of our target quasars. None of these shows significant (greater than 30%) optical variability over the time interval of a few years (in the observed frame) between the SDSS and HET observations.

Key words: early universe — galaxies: active — galaxies: high-redshift — quasars: general — X-rays

1. INTRODUCTION

One of the main themes in modern astronomy is the study of the earliest massive objects to form in the universe, now known as far back as the end of the reionization epoch (e.g., Rees 1999; Loeb & Barkana 2001; Fan et al. 2002; Hu et al. 2002). Quasars at $z \gtrsim 4$ can be studied in detail; because of their large broadband luminosities, they are typically detectable at most wavelengths [e.g., in the radio, Schmidt et al. 1995; Stern et al. 2000; in the millimeter, Omont et al. 2001; Carilli et al. 2001; in the submillimeter, McMahon et al. 1999; Isaak et al. 2002; in the near-infrared, Barkhouse & Hall 2001; Pentericci et al. 2003; in the optical, Schneider, Schmidt, & Gunn 1989; Fan et al. 2001; in the X-ray band, Kaspi, Brandt, & Schneider 2000 (hereafter KBS00); Vignali et al. 2001a, 2003 (hereafter V01a and V03, respectively); Bechtold et al. 2003]. Ground-based, large-area optical surveys, such as the Sloan Digital Sky Survey (SDSS; York et al. 2000), the Automatic Plate Measuring facility survey (BRI; Irwin, McMahon, & Hazard 1991), and the Palomar Digital Sky Survey (PSS; Djorgovski et al. 1998), have discovered more than 300 quasars at $z \geq 4$ thus far up to $z = 6.43$ (Fan et al. 2003).[6]

To extend our knowledge of the X-ray properties of $z \geq 4$ quasars, we have started a program to observe, with *Chandra* and *XMM-Newton*, both the optically most luminous ($M_B \approx -28.4$ to -30.2) $z \approx 4.1$–4.5 PSS/BRI quasars (e.g., V03) and the higher redshift, optically fainter SDSS quasars (V01a; Brandt et al. 2002; see Brandt et al. 2003 for a recent review). Selecting $z \geq 4$ quasar samples for X-ray observations in two different regions of the luminosity-redshift parameter space allows study of any dependence of the X-ray properties upon the optical selection criteria. In particular, it is possible to test for dependencies of $z \geq 4$ quasar X-ray continua on optical luminosity or redshift.

Here we report the results obtained from 11 *Chandra* observations and one *XMM-Newton* observation of a sample of 13 high-redshift ($z \approx 4.7$–5.4), moderately luminous ($M_B \approx -26.1$ to -28.5) quasars, mostly discovered by the SDSS and published in Anderson et al. (2001). One of these quasars (RD 657; Djorgovski et al. 2003) was serendipitously observed and detected in the *XMM-Newton* observation (i.e., there were two objects in one field). The only target quasar not coming from the SDSS data is BR B0305−4957 (Storrie-Lombardi et al. 2001; Peroux et al. 2001).

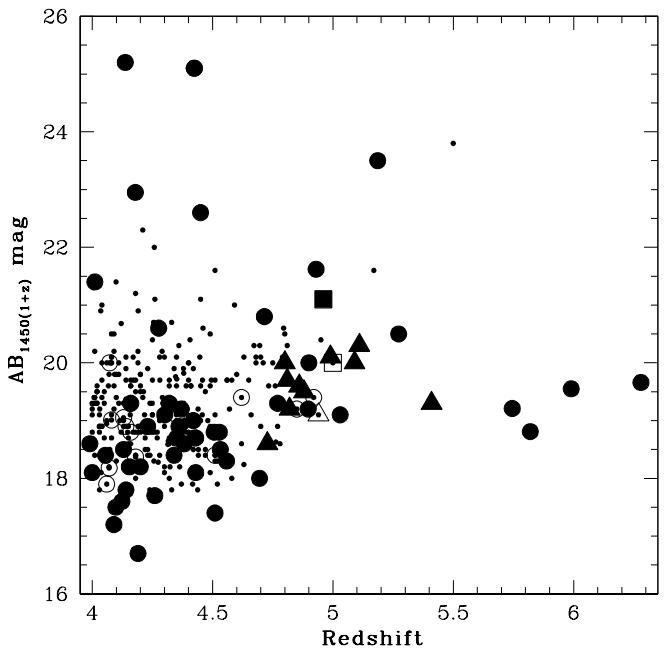

FIG. 1.—$AB_{1450(1+z)}$ vs. redshift for the known $z \geq 4$ AGNs [*small dots*; taken from Djorgovski as of 2002 July (see footnote 6)]. The X-ray–detected (undetected) quasars presented in this paper are shown as filled (open) triangles (*Chandra* observations) and a filled (open) square (*XMM-Newton* observation). Filled and open circles indicate $z \geq 4$ X-ray–detected AGNs and tight upper limits, respectively, from previous observations [Schneider et al. 1998; Waddington et al. 1999 (note that this identification is still debated; L. L. Cowie 2002, private communication); KBS00; V01a; Brandt et al. 2001, 2002; Silverman et al. 2002; Vignali et al. 2002; Barger et al. 2002; Bechtold et al. 2003; V03; Castander et al. 2003], most of which were performed by *Chandra* and *ROSAT*.

Given that the accretion rate (relative to the Eddington rate) of quasars may increase with redshift (e.g., Kauffmann & Haehnelt 2000), the first quasars could show unusual phenomena such as "trapping radius" effects (e.g., Begelman 1979) or accretion disk instabilities (e.g., Lightman & Eardley 1974). Furthermore, our targets are bright enough to assure in most cases X-ray detections with snapshot (e.g., ≈4–10 ks) observations, given the correlation found between $AB_{1450(1+z)}$ magnitude and soft X-ray flux (see, e.g., V01a; V03). The number of $z \geq 4.8$ X-ray–detected quasars is approximately doubled by the objects presented here. As shown in Figure 1, where the $AB_{1450(1+z)}$ magnitude is plotted as a function of redshift, the objects presented in this paper suitably complement previous X-ray studies of $z \geq 4$ quasars. All but one of these quasars are likely radio-quiet (see § 3 for details). Hereafter, we adopt $H_0 = 70$ km s^{-1} Mpc^{-1} in a Λ-cosmology with $\Omega_M = 0.3$ and $\Omega_\Lambda = 0.7$ (e.g., Turner 2002).

2. OBSERVATIONS AND DATA REDUCTION

2.1. *Chandra Observations*

Eleven of the 13 quasars were observed by *Chandra* during Cycle 3 with ≈3.7–9.8 ks observations (see Table 1; hereafter all of the quasars will be referred to via their abbreviated names).

All of the sources were observed with the Advanced CCD Imaging Spectrometer (ACIS; Garmire et al. 2003) with the S3 CCD at the aim point. Faint mode was used for the event telemetry format, and *ASCA* grade 0, 2, 3, 4, and 6 events were used in the analysis. This particular grade selection is standard and appears to optimize the signal-to-background ratio (see § 6.3 of the *Chandra* Proposers' Observatory Guide). Source detection was carried out with WAVDETECT (Freeman et al. 2002). We used wavelet transforms (using a Mexican hat kernel) with wavelet scale sizes of 1, 1.4, 2, 2.8, and 4 pixels and a false-positive probability threshold of 10^{-4}. Given the small number of pixels being searched due to the known source positions and the excellent angular resolution of *Chandra*, the probability of

NOTES.—Units of right ascension are hours, minutes, and seconds, and units of declination are degrees, arcminutes, and arcseconds. The optical information for the quasars presented here can be found in the papers cited in the reference column. For BR B0305−4957, we use the redshift $z = 4.73$ from Peroux et al. (2001) derived from two emission lines (Si IV–O IV] and C IV) in their high-quality optical spectrum. Storrie-Lombardi et al. (2001) reported $z = 4.78$ (see their Table 1) and $z = 4.82$ (see their Fig. 3) derived from a lower quality optical spectrum with less wavelength coverage.

[a] Distance between the optical and X-ray positions; a blank entry indicates no X-ray detection.

[b] The *Chandra* exposure time has been corrected for detector dead time. The *XMM-Newton* exposure time, computed from the exposure maps (i.e., taking into account the decreasing effective exposure at increasing off-axis angles from the aim point), is for the observation after the background flares have been removed (see § 2.2).

[c] *XMM-Newton* observation.

[a] Errors on the X-ray counts were computed according to Tables 1 and 2 of Gehrels (1986) and correspond to the 1 σ level; these were calculated using Poisson statistics. The upper limits are at the 95% confidence level and were computed according to Kraft, Burrows, & Nousek (1991).

spurious detections is extremely low; most of the sources were in fact detected at a false-positive probability threshold of 10^{-6}. Typically, detections were achieved with a wavelet scale of 1.4 pixels or less.

Source searching was performed in four energy ranges for consistency with our previous work (V01a; V03): the ultrasoft band (0.3–0.5 keV), the soft band (0.5–2 keV), the hard band (2–8 keV), and the full band (0.5–8 keV); in the redshift range of $z \approx 4.7$–5.4 covered by our sample, the full band corresponds to the ≈2.8–51 keV rest-frame band. All but one of the sources observed by *Chandra* were detected. The *Chandra* positions of the detected quasars were found to lie within 0.″2–0.″8 of their optical positions (see Table 1); this is consistent with the expected positional error. Given the X-ray weakness of SDSS 0756+4502 (two full-band counts), we will discuss the reliability of its detection in more detail in § 2.1.1. The *Chandra* nondetection, SDSS 1737+5828, will be discussed further in § 4.1.

The WAVDETECT photometric measurements are shown in Table 2; they are consistent with independent measurements obtained using manual aperture photometry and a 2″ radius circular cell. Background is typically negligible in the source extraction region, except for SDSS 0941+5947, where the observation is partially affected by a background flare; this is taken into account in Table 2. The only object with enough counts to derive a useful power-law photon index via direct X-ray spectral analysis is SDSS 0231−0728. Assuming only Galactic absorption, it has $\Gamma = 2.4^{+0.7}_{-0.6}$ using the unbinned data and the *C*-statistic (Cash 1979) with XSPEC Version 11.2.0 (Arnaud 1996); errors are at the 90% confidence level for one interesting parameter ($\Delta C = 2.71$; Avni 1976; Cash 1979).[7] This photon index is consistent, within the errors, with those of $z \approx 0$–3 quasars in the rest-frame 2–10 keV band ($\Gamma \approx 1.7$–2.3; e.g., George et al. 2000; Mineo et al. 2000; Reeves & Turner 2000; Page et al. 2003).

[7] To account for the quantum efficiency decay of ACIS at low energies, possibly caused by molecular contamination of the ACIS filters, we have applied a time-dependent correction to the ACIS quantum efficiency. We generated new ARFs, which have been used in the X-ray spectral analyses presented throughout this paper.

The soft-band images of the detected quasars (full-band image for BR 0305−4957), adaptively smoothed using the algorithm of Ebeling, White, & Rangarajan (2003), are shown in Figure 2.

2.1.1. *Chandra Detection of SDSS 0756+4502*

Similarly to the $z = 5.27$ quasar SDSS 1208+0010 presented in § 2.2 of V01a, SDSS 0756+4502 ($z = 4.80$) shows only two X-ray photons (both in the observed 0.5–2 keV band) within 0.″7 of the optical position of the source. The source is detected by WAVDETECT using a false-positive threshold of 10^{-4}. To investigate further whether the SDSS 0756+4502 X-ray detection can be considered real, we extracted a 400×400 pixel^2 (≈200×200 arcsec^2) region centered on the optical position of the quasar, excluding the immediate vicinity of the quasar itself. We covered this region with 30,000 circles of 1″ radius whose centers were randomly chosen. The choice of the 1″ radius aperture appears reasonable, since the full-band 80% encircled-energy radius for on-axis sources is ≈0.″69 (see Fig. 6.3 of the *Chandra* Proposers' Observatory Guide) and the average positional error for the other quasars detected by *Chandra* is ≈0.″5. The counts obtained in each circle were averaged, giving 0.060 counts circle^{-1} in the full band and 0.022 counts circle^{-1} in the soft band. The Poisson probabilities of obtaining two counts or more when 0.060 and 0.022 counts are expected are $\approx 1.7 \times 10^{-3}$ and $\approx 2.4 \times 10^{-4}$, corresponding to one-tailed Gaussian probabilities of ≈3.3 σ and ≈3.9 σ, respectively.

We have directly verified the validity of the Poisson approximation for the SDSS 0756+4502 field using the count distribution from the 30,000-circle analysis described above. The results of our simulations are in reasonable agreement with the Poisson probabilities. Therefore, in the following, SDSS 0756+4502 will be considered detected by *Chandra*.

2.1.2. *X-Ray Sources Close to the Quasars*

Following the method used in § 3.4 of V03, we have searched for possible companions for all of the objects observed by *Chandra* over a region of ≈100″ × 100″ centered on the quasars (see Fig. 2), corresponding to a physical scale of $\approx 630 \times 630$ kpc^2 at the average redshift of our sample ($z \approx 5.0$). Approximately one faint serendipitous X-ray source is found in each quasar field. A comparison of their 0.5–2 keV cumulative number counts (excluding, of course, the quasars themselves) with those obtained from the *ROSAT* deep survey of the Lockman Hole (Hasinger et al. 1998) and the *XMM-Newton* moderately deep survey HELLAS2XMM (Baldi et al. 2002) indicates that in the proximity of the SDSS quasars there is no evidence for an X-ray source overdensity. We found a surface density of $N(>S) = 751^{+451}_{-301}$ deg^{-2} for the X-ray sources surrounding our SDSS targets (where S is the soft X-ray flux limit we reached with the present observations: $\approx 2 \times 10^{-15}$ ergs cm^{-2} s^{-1}).

2.1.3. *X-Ray Extension of the Quasars*

To constrain the presence of gravitational lensing (e.g., Barkana & Loeb 2000; Comerford, Haiman, & Schaye 2002; Wyithe & Loeb 2002), X-ray jets close to the quasars (e.g., Schwartz 2002), and X-ray scattering by dust in the intergalactic medium (e.g., Telis et al. 2003), we performed

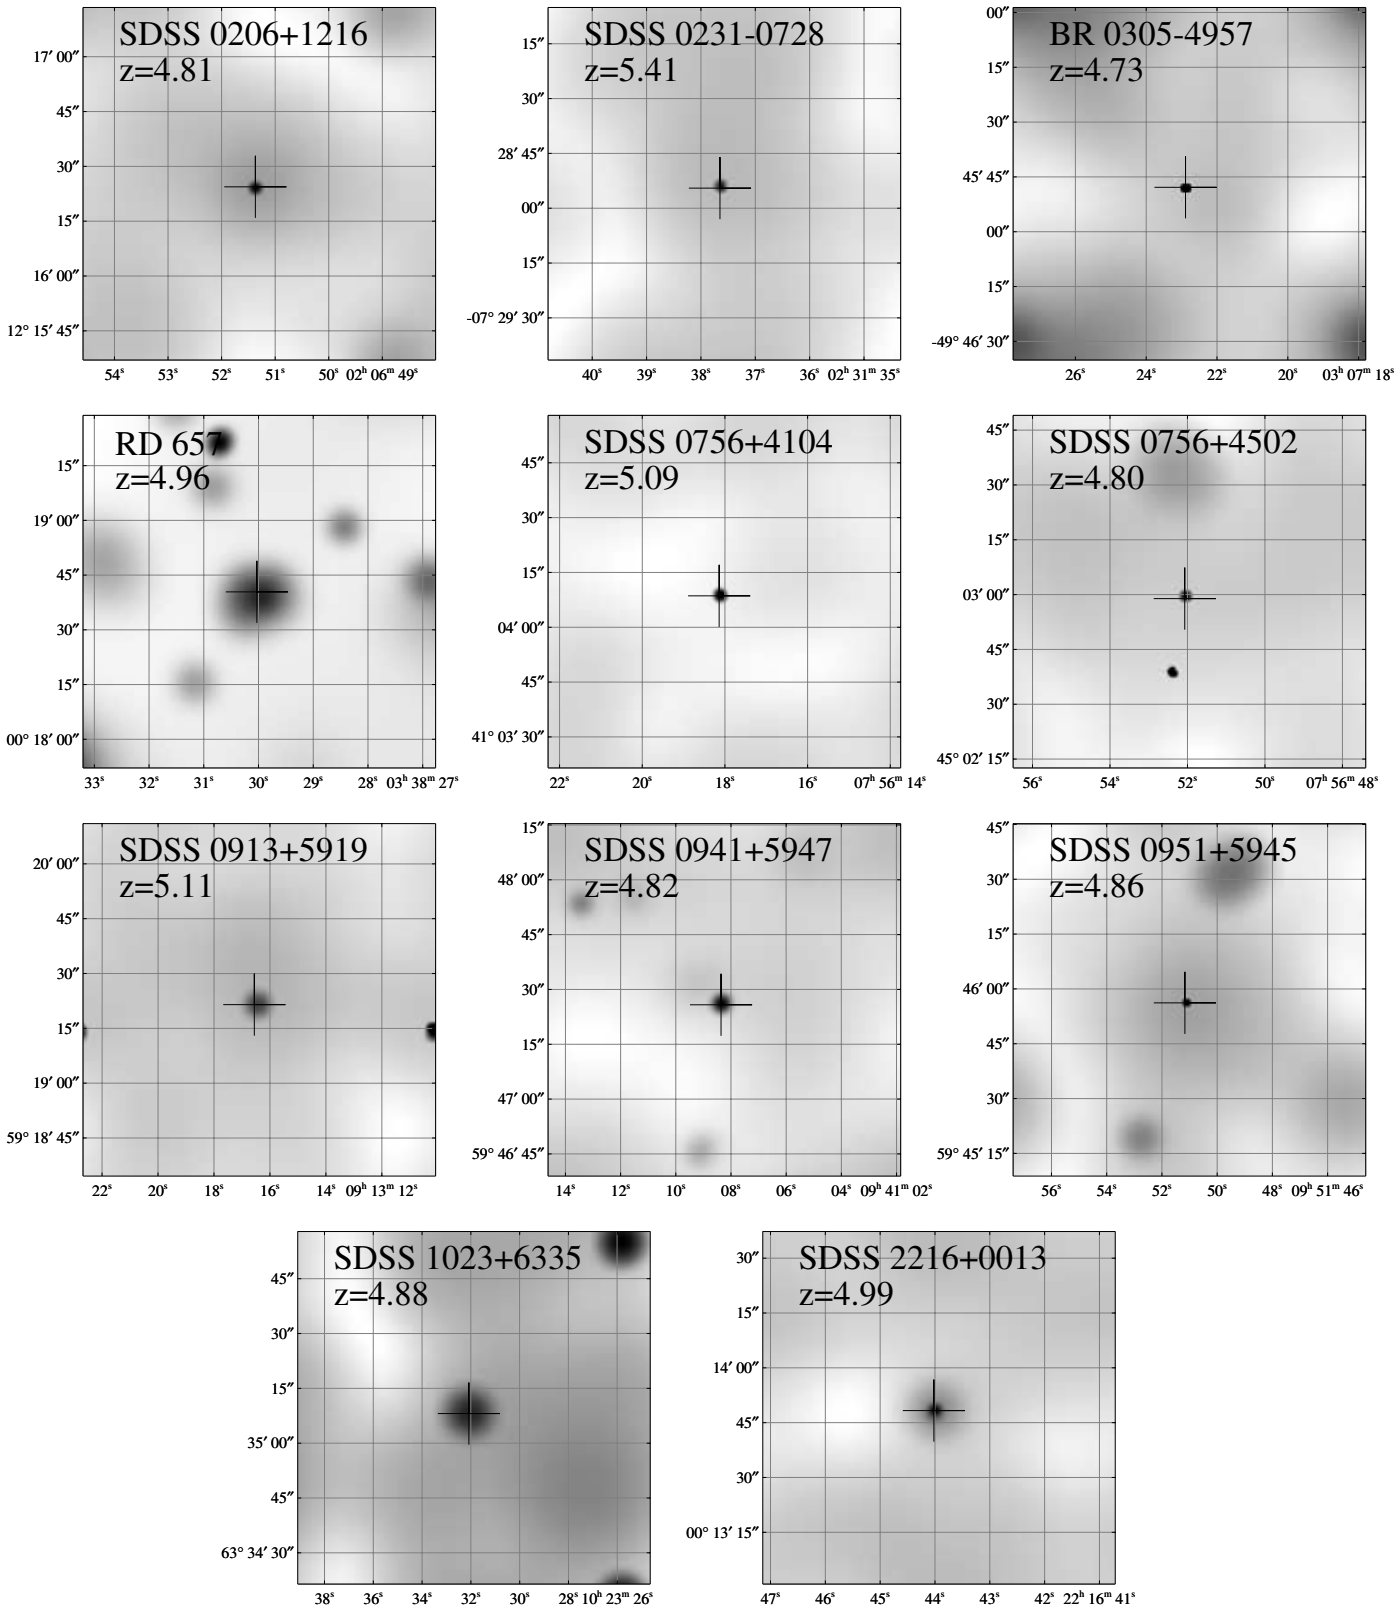

FIG. 2.—*Chandra* 0.5–2 keV (0.5–8 keV for BR 0305−4957) and *XMM-Newton* 0.3–12 keV (for RD 657) images of the X-ray–detected quasars presented in this paper. In each panel, the horizontal axis shows the right ascension, and the vertical axis shows the declination (both in J2000.0 coordinates). North is up, and east to the left. The images are 97″ × 97″and have been adaptively smoothed at the 2 σ level [except for BR 0305−4957, RD 657, SDSS 0951+5945 (1.5 σ level), and SDSS 0756+4502 (1.3 σ level)] using the algorithm of Ebeling et al. (2003). Crosses mark the optical positions of the quasars. The image of RD 657 does not cover the position of SDSS 0338+0021, since the two quasars are separated by 196″.

an analysis of X-ray extension for all the quasars observed by *Chandra* following the procedure described in § 3.5 of V03. All of the quasars' X-ray images are consistent with the sources being pointlike. The separation between multiply imaged sources at $z \approx 4$–5 is expected to be $\approx 1''$–$2''$ (Barkana & Loeb 2000). Typical flux ratios of multiply imaged quasars at high redshift are ≈2–8 (G. Chartas 2003, private communication), being strongly dependent on the shape, mass, redshift, and location of the lensing system. Given the limited number of counts for our detected sources, we expect that only in ≈30% of the present sample would we be able to detect such multiple images.

2.1.4. *X-Ray Variability of the Quasars*

Given tentative reports of increasing quasar X-ray variability with redshift (in the sense that quasars of the same X-ray luminosity are more variable at $z > 2$; Manners, Almaini, & Lawrence 2002), we have searched for X-ray variability by analyzing the photon arrival times in the 0.5–8 keV band using the Kolmogorov-Smirnov test. No significant variability was detected from any of our quasars. We note, however, that the analysis of X-ray variability for the quasars studied here is limited by both the short X-ray exposures in the rest frame (≈15 minutes; see Table 1) and the low X-ray fluxes of most of our quasars.

2.2. *XMM-Newton Observation*

The SDSS 0338+0021 field was observed by *XMM-Newton* for a nominal exposure time of 20.0 ks with the European Photon Imaging Camera (EPIC) pn (Strüder et al. 2001) and for 22.3 ks with the EPIC MOS (Turner et al. 2001) instruments. The data obtained with the Reflection Grating Spectrometer (den Herder et al. 2001), with a nominal exposure time of 22.8 ks, will not be considered in the following given the weakness of the target. Both the pn and MOS data were acquired in the "full-frame mode" using the thin filter (due to the likely weakness of the target in the X-ray band). The data were reduced with the *XMM-Newton* Science Analysis Software (SAS, Version 5.3.3) with the latest calibration products; we used the EPCHAIN and EMPROC tasks to generate valid photon lists. We filtered the data to avoid background flares (due to ≈100 keV protons; e.g., De Luca & Molendi 2002), which affect most of this *XMM-Newton* observation. To select good time intervals, we apply thresholds of 0.35 counts s^{-1} and 0.15 counts s^{-1} to pn and MOS data in the 10–12.4 keV and 10–13 keV energy bands, respectively (A. Baldi 2002, private communication). In these energy bands, the counts are mostly from the background. The final, on-axis useful exposure time for this observation is 5.5 ks for pn and MOS. Both single-pixel and double-pixel events (patterns 0–4) were used when extracting the pn counts, while patterns 0–12 were used for the MOS.

We performed source detection in the 0.3–2 keV, 0.5–2 keV, 0.5–10 keV, 2–10 keV, and 0.3–12 keV bands using the tasks EBOXDETECT and EMLDETECT and adopting a detection likelihood threshold of 10, corresponding to the ≈4 σ detection level. We did not consider the energy range below 0.3 keV because of the enhanced background at low photon energies. The target, SDSS 0338+0021, was detected in none of the bands; its X-ray nondetection will be discussed further in § 4.1.

After our *XMM-Newton* observation was assigned, Djorgovski et al. (2003) found a $z = 4.96$ quasar (RD 657) located 196″ from the optical position of SDSS 0338+0021. In the *XMM-Newton* pn field of view, we found a 4.3 σ X-ray source detected 1.″7 from the optical position of RD 657 (see Table 1) in the 0.3–12 keV band ($15.3^{+5.0}_{-3.9}$ counts). We note the *XMM-Newton* positional error is larger (≈4″–5″; Metcalfe 2002) than that of *Chandra*; therefore, the X-ray and optical positions are consistent. Assuming the integral 0.5–2 keV number counts of Hasinger et al. (1998) and an X-ray error circle of 1.″7, we expect $\approx 2.5 \times 10^{-4}$ spurious associations given the soft X-ray flux of this source (3.6×10^{-15} ergs cm^{-2} s^{-1}; see Table 3). Therefore, we are confident that the serendipitously detected X-ray emission is associated with RD 657. For this source, we compared the 4.3 σ detection obtained by the SAS detection tasks with that obtained in a different way with SExtractor (Bertin & Arnouts 1996), finding similar results in both the number of counts and the significance of the source (3.6 σ).

Inspection of the X-ray image at the source position confirms the X-ray detection (see Fig. 2 for the 1.5 σ level adaptively smoothed image in the 0.3–12 keV band). RD 657 also seems to be present in the 0.3–2 keV adaptively smoothed image, although the quasar is not detected in this band by the SAS procedure described above. Even though there has been speculation that SDSS 0338+0021 and RD 657 mark a large-scale structure, perhaps a protocluster at $z \approx 5$ (Djorgovski et al. 2003), we found no clear evidence for diffuse X-ray emission or an overdensity of X-ray sources around these two quasars. Our constraints are not tight, however, due to the short exposure time and relatively high background of *XMM-Newton*. Since the background in the *XMM-Newton* observation is higher and more complex than in the *Chandra* observations, for SDSS 0338+0021 and RD 657 we do not report the counts in individual bands but directly derived the main X-ray parameters in Table 3 (see § 3). We have also analyzed the *XMM-Newton* data with less conservative background screening choices and our main results are unchanged; SDSS 0338+0021 is not detected and RD 657 is detected.

2.3. *Hobby-Eberly Telescope Observations*

Given that quasars frequently vary in both the optical and X-ray bands, one must be concerned about the reliability of the frequently employed optical–to–X-ray power-law slope whenever observations in the two bands are not simultaneous. To search for optical variability, eight of the 13 quasars in our sample were observed with the 9 m Hobby-Eberly Telescope (HET; Ramsey et al. 1998).[8] Short (2 minutes; 4 minutes for SDSS 0941+5947) *I*-band images of the quasar fields were taken with the HET's Marcario Low-Resolution Spectrograph (LRS; Hill et al. 1998a, 1998b; Cobos Duenas et al. 1998) generally within 1–2 months of the X-ray observations (1–2 weeks in the rest frame; see Table 1).[9] The HET images covered fields ≈4′ on a side, and using the published finding charts of the fields it was possible to obtain an approximate photometric calibration

[8] HET observations were not performed for SDSS 0231−0728, BR 0305−4957, SDSS 0338+0021, RD 657, and SDSS 1023+6335.

[9] The only exception is SDSS 0756+4502, observed by the HET 10 months before the X-ray observation.

TABLE 3

OPTICAL, X-RAY, AND RADIO PROPERTIES OF $z > 4.7$ QUASARS OBSERVED BY *Chandra* AND *XMM-Newton*

Object (1)	N_H[a] (2)	$AB_{1450(1+z)}$ (3)	$f_{2500Å}$[b] (4)	$\log(\nu L_\nu)_{2500Å}$ (5)	M_B (6)	Count Rate[c] (7)	f_X[d] (8)	f_{2keV}[e] (9)	$\log(\nu L_\nu)_{2keV}$ (10)	$\log(L_{2-10keV})$[f] (11)	α_{ox}[g] (12)	R[h] (13)

NOTES.—Luminosities are computed using $H_0 = 70$ km s^{-1} Mpc^{-1}, $\Omega_M = 0.3$, and $\Omega_\Lambda = 0.7$.

[a] From Dickey & Lockman 1990 in units of 10^{20} cm^{-2}.

[b] Rest-frame 2500 Å flux density in units of 10^{-27} ergs cm^{-2} s^{-1} Hz^{-1}.

[c] Observed count rate computed in the 0.5–2 keV band in units of 10^{-3} counts s^{-1}.

[d] Galactic absorption-corrected flux in the observed 0.5–2 keV band in units of 10^{-15} ergs cm^{-2} s^{-1}. These fluxes and the following X-ray parameters have been corrected for the ACIS quantum efficiency decay at low energy.

[e] Rest-frame 2 keV flux density in units of 10^{-32} ergs cm^{-2} s^{-1} Hz^{-1}.

[f] Rest-frame 2–10 keV luminosity corrected for Galactic absorption in units of ergs s^{-1}.

[g] Errors have been computed following the " numerical method " described in § 1.7.3 of Lyons (1991); both the statistical uncertainties on the X-ray count rates and the effects of the observed ranges of the X-ray and optical continuum shapes have been taken into account (see the text for details; see also § 3 in V01a).

[h] Radio-loudness parameter, defined as $R = f_{5GHz}/f_{4400Å}$ (rest frame; e.g., Kellermann et al. 1989). The rest-frame 5 GHz flux density is computed from the observed 1.4 GHz flux density assuming a radio power-law slope of $\alpha = -0.8$ with $f_\nu \propto \nu^\alpha$.

[i] 1.4 GHz flux density from NVSS (Condon et al. 1998).

[j] 1.4 GHz flux density from FIRST (Becker et al. 1995).

[k] No radio data are available.

[l] The soft X-ray flux and the subsequent X-ray parameters have been computed from the 0.3–12 keV counts, where the source is detected.

using stellar objects in the fields. Although it is difficult to give precise estimates given the difference between the LRS and SDSS bandpasses, it is clear that none of the quasars observed with the HET has varied significantly (by $\gtrsim 30\%$) in brightness from its published value.

These constraints on the optical flux variability allow for at most an uncertainty of ≈ 0.05 in the α_{ox} determination (see § 3). The lack of large brightness variations in the sample is not surprising considering the relatively small amount of time in the rest frame (several months) between the SDSS photometry and the X-ray/HET observations.

To investigate the nature of SDSS 1737+5828, the only quasar that was not detected in the *Chandra* observations, we performed a 30 minute LRS spectroscopic observation. This was taken with the 300 line mm^{-1} grating, an OG515 blocking filter, and a slit width of $2''$ (with a seeing of $\approx 1''.6$), providing a spectrum in the wavelength range 5100–10200 Å at a resolving power of $\approx$240–300. The spectroscopic data were reduced using standard IRAF routines. The wavelength calibration was performed using a Ne arc lamp, while the flux calibration was achieved using the standard star BD $+17^{\circ}4708$, observed during the same night. The HET spectrum (Fig. 3, *black curve*) is discussed in § 4.1 along with the SDSS spectrum (adapted from Anderson et al. 2001; Fig. 3, *gray curve*). A direct comparison of the continuum levels of the two spectra is difficult. While the uncertainty in the calibration of the SDSS spectrum is less than $\approx 20\%$, it is hard to obtain an accurate HET flux calibration mostly because of the variations of effective aperture produced by its optical design (in addition to problems due to slit losses).

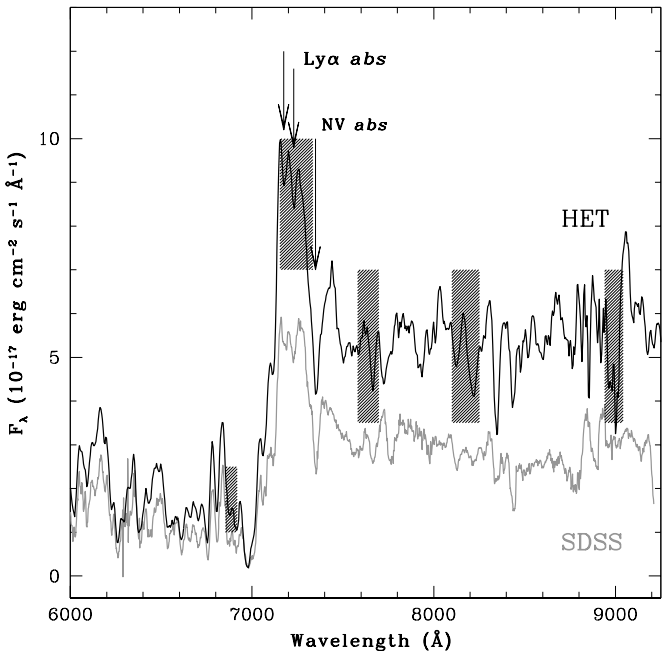

FIG. 3.—Optical spectra of SDSS 1737+5828 obtained with the HET (30 minute exposure; *black curve*) and by the SDSS (adapted from Anderson et al. 2001; *gray curve*). No correction for the telluric lines has been applied to the HET spectrum (the affected regions of the HET spectrum are shaded). The likely absorption features from N v and Lyα are shown (see § 4.1 for details).

3. MULTIWAVELENGTH PROPERTIES OF $z > 4.7$ QUASARS

The principal optical, X-ray, and radio properties of the quasars in our sample are shown in Table 3. A description is as follows:

Column (1).—The abbreviated name of the source.

Column (2).—The Galactic column density (from Dickey & Lockman 1990) in units of 10^{20} cm^{-2}.

Column (3).—The monochromatic rest-frame $AB_{1450(1+z)}$ magnitude (defined in § 3b of Schneider et al. 1989) with estimated errors ≈ 0.1 mag. The absolute photometry is correct to within ≈ 0.05 mag (Anderson et al. 2001), while the computation of the $AB_{1450(1+z)}$ magnitude using the photometric measurements and the composite SDSS quasar spectrum (Vanden Berk et al. 2001) is correct to within $\approx$0.05–0.10 mag.

Columns (4) and (5).—The 2500 Å rest-frame flux density and luminosity. These were computed from the $AB_{1450(1+z)}$ magnitude assuming an optical power-law slope of $\alpha = -0.79$ ($S_\nu \propto \nu^\alpha$; Fan et al. 2001) to allow direct comparison with the results presented in V01a and V03. The 2500 Å rest-frame flux densities and luminosities are reduced by $\approx 15\%$ when the power-law slope of the optical continuum is changed to $\alpha = -0.5$ (e.g., Vanden Berk et al. 2001; Schneider et al. 2001).

Column (6).—The absolute *B*-band magnitude computed using $\alpha = -0.79$. If $\alpha = -0.5$ is adopted for the extrapolation, the absolute *B*-band magnitudes are fainter by ≈ 0.35 mag.

Columns (7) and (8).—The observed count rate in the 0.5–2 keV band and the corresponding flux (F_X), corrected for Galactic absorption. This flux has been calculated using PIMMS (Version 3.2d; Mukai 2002) and a power-law model with $\Gamma = 2.0$, as derived for samples of $z \approx 0$–3 quasars (e.g., George et al. 2000; Mineo et al. 2000; Reeves & Turner 2000; Page et al. 2003) and $z > 4$ optically luminous, PSS quasars (V03; see also § 4.3).

The X-ray fluxes reported in this paper have been corrected for the ACIS quantum efficiency decay at low energy (see footnote 7). For each quasar, we produced an ancillary response file (ARF) assuming an exponential decay for the ACIS quantum efficiency. From each ARF, we derived an effective area that was used to replace the original ACIS-S effective area in PIMMS. The 0.5–2 keV flux correction is $\approx 20\%$ for the *Chandra* observations presented here. All of the parameters derived from the measured soft X-ray flux have been corrected. Following this procedure, we also corrected all of the X-ray fluxes of the $z \geq 4$ quasars previously observed by *Chandra* (see Table A1 in the Appendix for an updated version of the relevant numbers for $z \geq 4$ quasars).[10]

The soft X-ray flux changes by $\approx$1%–2% over a reasonable range in the adopted power-law photon index, $\Gamma = 1.7$–2.3. The soft X-ray flux derived from the 0.5–2 keV counts is generally similar (to within $\approx$5%–20%) to that derived from the 0.5–8 keV counts.

For RD 657, the 0.5–2 keV flux and subsequent X-ray parameters reported below have been derived using the counts in the 0.3–12 keV band, where it was detected.

[10] Also see http://www.astro.psu.edu/users/niel/papers/.

Columns (9) and (10).—The rest-frame 2 keV flux density and luminosity, computed assuming $\Gamma = 2.0$.

Column (11).—The 2–10 keV rest-frame luminosity, corrected for Galactic absorption.

Column (12).—The optical–to–X-ray power-law slope, α_{ox}, defined as

$$\alpha_{ox} = \frac{\log(f_{2keV}/f_{2500\text{Å}})}{\log(\nu_{2keV}/\nu_{2500\text{Å}})}\ , \quad (1)$$

where f_{2keV} and $f_{2500\text{Å}}$ are the rest-frame flux densities at 2 keV and 2500 Å, respectively. The $\approx 1\ \sigma$ errors on α_{ox} have been computed following the "numerical method" described in § 1.7.3 of Lyons (1991). Both the statistical uncertainties on the X-ray count rates and the effects of possible changes in the X-ray ($\Gamma \approx 1.7$–2.3) and optical ($\alpha \approx -0.5$ to -0.9; Schneider et al. 2001) continuum shapes have been taken into account (see § 3 of V01a for further details). Changing the power-law slope of the optical continuum from $\alpha = -0.79$ to -0.5 induces a small increase in the α_{ox} values (more positive by ≈ 0.03).

Column (13). — The radio-loudness parameter (e.g., Kellermann et al. 1989), defined as $R = f_{5GHz}/f_{4400\text{Å}}$ (rest frame). The rest-frame 5 GHz flux density was computed from the FIRST (Becker, White, & Helfand 1995) or NVSS (Condon et al. 1998) observed 1.4 GHz flux density assuming a radio power-law slope of $\alpha = -0.8$. The upper limits reported in the table are at the $3\ \sigma$ level. The rest-frame 4400 Å flux density was computed from the $AB_{1450(1+z)}$ magnitude assuming an optical power-law slope of $\alpha = -0.79$. Radio-loud quasars (RLQs) have $R > 100$, whereas radio-quiet quasars (RQQs) are characterized by $R < 10$ (e.g., Kellermann et al. 1989).

SDSS 0913+5919 is the only radio-loud object ($R \approx 411$) in our sample and is also the highest redshift ($z = 5.11$) RLQ thus far detected in the X-ray band. For one quasar, BR 0305−4957, no radio data are available. None of the remaining quasars is a RLQ, although in some cases the observed-frame 1.4 GHz flux density constraints provided by the NVSS are not sufficiently tight to prove that a quasar is radio-quiet ($R < 10$); at most, these objects could be radio-moderate (see Table 3). Given that ≈85%–90% of the quasar population is radio-quiet (e.g., Stern et al. 2000), we expect the majority of the quasars with radio-loudness upper limits of 10–100 to be radio-quiet.

4. DISCUSSION

Thanks mostly to *Chandra* (e.g., V01a; Brandt et al. 2002; Bechtold et al. 2003; V03) and *ROSAT* (e.g., KBS00; V03) observations, we have seen a substantial growth in the data needed to study the X-ray properties of $z \geq 4$ quasars. At present, there are ≈70 quasars at $z \geq 4$ with X-ray detections.[11]

Figure 4 shows the observed-frame, Galactic absorption-corrected 0.5–2 keV flux versus $AB_{1450(1+z)}$ magnitude for a compilation of $z \geq 4$ active galactic nuclei (AGNs). The detected objects presented in this paper are shown as filled triangles (10 *Chandra* detections) and a filled square (one *XMM-Newton* detection), while large and thick downward-pointing arrows indicate the two quasars in our sample with X-ray upper limits. Because this figure is constructed from *directly observed* physical quantities, it is robust and useful for planning future X-ray observations of high-redshift quasars. We present a complementary discussion based on α_{ox}, a parameter somewhat less directly tied to observation, in § 4.2.

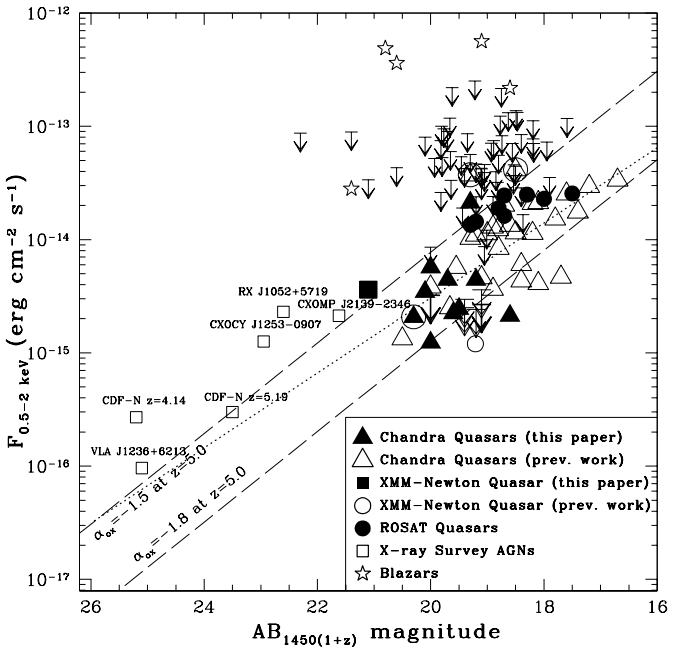

FIG. 4.—Observed-frame, Galactic absorption-corrected 0.5–2 keV flux vs. $AB_{1450(1+z)}$ magnitude for $z \geq 4$ AGNs. Object types are shown in the key. In particular, the objects presented in this paper are plotted as filled triangles (*Chandra* detections) and a filled square (*XMM-Newton* detection), while large, thick, downward-pointing arrows indicate X-ray upper limits for the objects of our sample. *Chandra* RLQs are plotted as circled triangles. *ROSAT* upper limits (*small downward-pointing arrows*) are at the $3\ \sigma$ confidence level. The slanted dashed lines show the $\alpha_{ox} = -1.5$ and $\alpha_{ox} = -1.8$ loci at $z = 5.0$ (the average redshift of the present sample). The dotted line shows the best-fit correlation reported in § 4 (eq. [2]) for the whole sample of $z \geq 4$ optically selected RQQs.

Quasars are well-known X-ray emitters at $z \approx 0$–3 (e.g., Vignali et al. 1999; Reeves & Turner 2000; Page et al. 2003). Figure 4 indicates that X-ray emission is also a universal property of $z \geq 4$ quasars.

Previous studies of $z \geq 4$ quasars have shown that there is a significant correlation between $AB_{1450(1+z)}$ and 0.5–2 keV flux (V01a; V03). The new X-ray detections and upper limits provided by the present work significantly improve the study of this correlation at fainter optical magnitudes. The average $AB_{1450(1+z)}$ magnitude of the sample presented here is 19.7, whereas the average for the bright PSS sample of V03 is 17.9. The presence of this correlation indicates that the same engine (namely accretion onto a supermassive black hole) is powering both the ultraviolet and X-ray emission. To study this correlation using all the available X-ray detections (41) and upper limits (52) for $z \geq 4$ optically selected RQQs (the majority of the objects plotted in Fig. 4), we have used the ASURV software package (revision 1.2; LaValley, Isobe, & Feigelson 1992). To evaluate the significance of the correlation, we used several methods available in ASURV, namely the Cox regression proportional hazard

[11] See http://www.astro.psu.edu/users/niel/papers/highz-xray-detected.dat for a regularly updated compilation of X-ray detections at $z \geq 4$.

(Cox 1972), the generalized Kendall τ (Brown, Hollander, & Korwar 1974), and the Spearman ρ models. We have chosen to use only optically selected RQQs in order to have a homogeneous sample (see § 4 of Vignali et al. 2002, hereafter V02, for the results of a sample of X-ray–selected quasars; also see Silverman et al. 2002 and Castander et al. 2003). Once the broad absorption line quasars (BALQSOs), which are known to be absorbed in the X-ray band (e.g., Brandt, Laor, & Wills 2000; Gallagher et al. 2001, 2002; Green et al. 2001; V01a), are excluded from the analysis (there are four in the original sample), we find that the $AB_{1450(1+z)}$ versus F_X correlation is significant at the greater than 99.9% level (all the tests above provide similar results). According to the EM (estimate and maximize) regression algorithm (Dempster, Laird, & Rubin 1977), the correlation is parameterized by

$$\log(F_X/\text{ergs cm}^{-2}\ \text{s}^{-1}) = [-(0.33 \pm 0.05)AB_{1450(1+z)} - (7.89 \pm 0.91)]\ , \quad (2)$$

which is plotted as a dotted line in Figure 4. Since $AB_{1450(1+z)} = -2.5 \log f_{1450\text{Å}} - 48.6$, the previous equation may also be written as

$$\log(F_X/\text{ergs cm}^{-2}\ \text{s}^{-1}) \propto (0.83 \pm 0.13) \log f_{1450\text{Å}}\ . \quad (3)$$

In Figure 5, the quantity $F_{X,obs}/F_{X,fit}$ is shown as a function of $AB_{1450(1+z)}$ magnitude for the $z \geq 4$ optically selected RQQs observed by *Chandra*. $F_{X,obs}$ represents the measured, Galactic absorption-corrected 0.5–2 keV flux and $F_{X,fit}$, the flux expected from the best-fit correlation above. The majority of the $z \geq 4$ quasars observed by *Chandra* are within a factor of 2 of the best-fit correlation. The only quasar clearly showing a large difference between the measured and expected fluxes is SDSS 0231−0728 (the brightest X-ray source in our sample). Since its X-ray emission is unlikely to be contaminated by nearby X-ray sources (see Fig. 2), it appears plausible that its unusually large X-ray flux is due to an episode of variability. Unfortunately, the lack of an HET observation for SDSS 0231−0728 does not allow us to examine this hypothesis further (assuming that the X-ray and optical variability are correlated). A constant fit to the data points of Figure 5 (including the associated errors, but excluding the upper limits) is statistically unacceptable ($\chi^2 = 54.6$ for 33 degrees of freedom). Excluding SDSS 0231−0728 improves the quality of the fit ($\chi^2 = 45.3$), although it remains unacceptable. This indicates that there is a real dispersion in the quantity plotted in Figure 5 above the statistical noise (see also § 4.2).

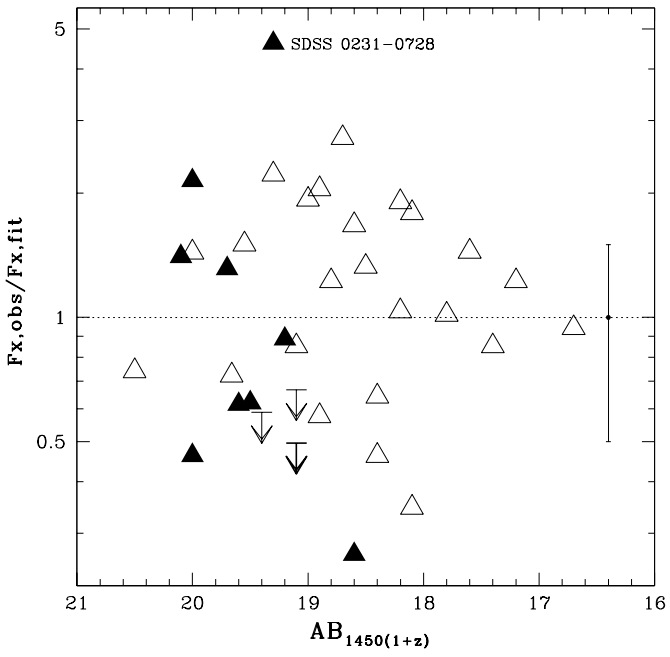

FIG. 5.—Plot of $F_{X,obs}/F_{X,fit}$ as a function of $AB_{1450(1+z)}$ magnitude for the $z \geq 4$ optically selected RQQs observed by *Chandra*. $F_{X,obs}$ represents the Galactic absorption-corrected 0.5–2 keV flux observed by *Chandra*, and $F_{X,fit}$ the flux expected on the basis of the best-fit correlation between the soft X-ray flux and $AB_{1450(1+z)}$ magnitude discussed in § 4 (eq. [2]). Symbols are the same as in Fig. 4. The dotted line indicates where the measured and expected fluxes are the same. To avoid symbol crowding, we have only shown a representative average uncertainty on the flux ratios (the error bar near the middle right).

4.1. *X-Ray Nondetections: Likely Explanations*

All but two (SDSS 0338+0021 and SDSS 1737+5828) of the quasars presented here have been detected in the X-ray band. The nondetection of SDSS 0338+0021 is probably due to the short exposure time of the *XMM-Newton* observation once the flaring-background intervals have been removed. Assuming the best-fit parameters of the $AB_{1450(1+z)}$ versus 0.5–2 keV flux correlation reported in equation (2), we would expect a 0.5–2 keV flux of $\approx 3.2 \times 10^{-15}$ ergs cm^{-2} s^{-1}. Although SDSS 0338+0021 was observed at the aim point, the on-axis flux limit of the *XMM-Newton* EPIC pn in a $\approx$5.5 ks exposure (see Table 1) is a factor of $\approx$2 higher than that achieved with *Chandra* in the same amount of time.

No *Chandra* source counts were detected at the optical position of SDSS 1737+5828. The faint *ROSAT* source reported as a possible counterpart of SDSS 1737+5828 by Anderson et al. (2001) is clearly present in the *Chandra* observation, but its X-ray position is 45″ from the quasar's optical position. There are two possible explanations for the SDSS 1737+5828 nondetection: this quasar is either strongly absorbed or intrinsically X-ray–weak. If the nondetection is due to the presence of intrinsic X-ray absorption, a column density of $N_H \gtrsim 1.2 \times 10^{23}$ cm^{-2} is necessary to reproduce the *Chandra* constraints (see Tables 2 and 3) assuming the average $\alpha_{ox} = -1.71$ of the sample (see § 4.2) and an X-ray photon index of $\Gamma = 2.0$. The absorption possibility finds partial support from the published SDSS 1737+5828 optical spectrum (Anderson et al. 2001; see Fig. 3, *gray curve*), which shows evidence of a strong, narrow N v absorption feature at $z \approx 4.92$. This absorption feature has a fairly high formal significance in the SDSS spectrum, but given the importance of the intrinsic absorption interpretation, we wished to acquire an independent confirmation of the line; the new observation would also allow an investigation of any line variability. We therefore obtained a 30 minute spectroscopic observation of SDSS 1737+5828 with the HET (see § 2.3). The resulting spectrum (Fig. 3, *black curve*) confirms the presence of a clear narrow N v absorption feature. This line is unresolved (the spectral resolution is $\approx$1000 km s^{-1}) and has a blueshift of $\approx$700 km s^{-1} relative to the quasar redshift of 4.94 reported by Anderson et al. (2001). In both the SDSS and HET spectra, we see evidence for narrow Lyα absorption spanning the redshift of the N v absorption feature with the strongest

absorption appearing at $z \approx 4.90$ and $z \approx 4.945$. There may be features at similar redshifts in Si IV and C IV, but the signal-to-noise ratio of the spectra prevents us from unambiguously identifying these systems. Nevertheless, the N V line alone strongly suggests that significant internal absorption is present in SDSS 1737+5828, since N V absorption of this strength is rarely caused by intervening galaxies (e.g., York et al. 1991), and the absorption is blueshifted with respect to the emission-line redshift. The Lyα emission line appears weak; the rest-frame equivalent width is only $\approx$35 Å. On average, the rest-frame equivalent width of Lyα + N V in high-redshift quasars is $\approx$70–80 Å (Schneider, Schmidt, & Gunn 1991; Fan et al. 2001). The evidence from the HET and SDSS spectra strongly suggests that significant internal absorption is present in SDSS 1737+5828, but the quasar is clearly not a strong high-redshift BALQSO such as SDSS 0856+5252 ($z = 4.79$; Anderson et al. 2001), SDSS 1044−0125 ($z = 5.74$; Fan et al. 2000; Brandt et al. 2001; Maiolino et al. 2001; Goodrich et al. 2001), or SDSS 1129−0142 ($z = 4.85$; Zheng et al. 2000).

4.2. α_{ox} *Results*

Previous reports (e.g., V01a; Bechtold et al. 2003; V03) of steeper α_{ox} indices for $z \gtrsim 4$ quasars than for lower luminosity, lower redshift quasars are confirmed by the present analysis (see Fig. 6). The 12 RQQs of our sample have $\langle\alpha_{ox}\rangle = -1.71 \pm 0.05$ (the error represents the standard deviation of the mean). This average α_{ox} value is considerably steeper than that obtained for, e.g., the Bright Quasar Survey (BQS; Schmidt & Green 1983) RQQs at $z < 0.5$ ($\langle\alpha_{ox}\rangle = -1.56 \pm 0.02$; see Brandt et al. 2000 and V01a). The sample of eight optically luminous $z > 4$ PSS RQQs presented in V03 has an even steeper average α_{ox} ($\langle\alpha_{ox}\rangle = -1.77 \pm 0.03$).[12] The PSS sample of V03 has $\langle\log(l_{2500\text{Å}}/\text{ergs s}^{-1}\text{ Hz}^{-1})\rangle = 32.2$, while the one presented here has $\langle\log(l_{2500\text{ Å}}/\text{ergs s}^{-1}\text{ Hz}^{-1})\rangle = 31.5$. According to the known anticorrelation between α_{ox} and 2500 Å luminosity (e.g., Avni, Worrall, & Morgan 1995; Vignali, Brandt, & Schneider 2003, hereafter VBS03; also see the discussion later in this subsection) following the equation[13]

$$\alpha_{ox} = -(0.095 \pm 0.021) l_{2500\text{Å}} + (1.295 \pm 0.648)\ , \quad (4)$$

we expect an average α_{ox} of −1.70 for the sample of RQQs presented here, in good agreement with the average α_{ox} value reported above. A summary of these results is shown in Figure 6: the α_{ox} distribution for the BQS RQQs (*top*) is clearly different from that of the $z \geq 4$ RQQs observed by *Chandra* thus far (*bottom*). In both α_{ox} distributions, some of the quasars with the steepest α_{ox} values are BALQSOs or mini-BALQSOs; areas with arrows indicate upper limits. The principal properties (redshifts, rest-frame 2500 Å and 2–10 keV luminosities, and α_{ox} values) of representative samples of RQQs at low and high redshifts are reported in Table 4.

We find no significant correlation of α_{ox} with either rest-frame 2500 Å luminosity or redshift using only the available $z \geq 4$ RQQs. However, we can also use the new X-ray detections and upper limits presented here to extend the VBS03 study of α_{ox} dependence upon 2500 Å luminosity and redshift.[14] As in VBS03, we mostly use the SDSS RQQs taken from the Early Data Release (EDR) quasar catalog (Schneider et al. 2002). In particular, at $z < 4$ we use the 128 EDR RQQs of VBS03 (see their § 3.1.1) covered by pointed *ROSAT* PSPC and HRI observations, with an overall X-ray detection fraction of $\approx$48%. At $z \geq 4$, we use all published *Chandra* (V01a; Brandt et al. 2002; Bechtold et al. 2003) and *XMM-Newton* (Brandt et al. 2001) observations of SDSS RQQs in addition to the ones presented in this paper. In total, we have 20 SDSS RQQ observations at $z > 4$ (including RD 657, observed in one of the fields surveyed by the SDSS; see § 2.2 and Djorgovski et al. 2003), 16 of which have X-ray detections. To improve the statistics at high luminosities and redshifts without introducing any evident bias (see § 3.2 of VBS03), we also include 15 PSS RQQs and seven BRI RQQs at $z \geq 4$ observed by *Chandra* (V01a; Bechtold et al. 2003; V03; Priddey et al. 2003); only one of these is not detected in the X-ray band (V01a).

Therefore, the final sample used in the present analysis is comprised of 170 RQQs ($\approx$58% with X-ray detections) over the redshift range $z \approx 0.2$–6.3 and the rest-frame 2500 Å luminosity range $\log(l_{2500\text{Å}}/\text{ergs s}^{-1}\text{ Hz}^{-1}) \approx 29.0$–32.6. Eleven of these quasars are known BALQSOs; results obtained both including and excluding BALQSOs are presented below. As luminosity is correlated with redshift in flux-limited samples, we use a partial correlation analysis technique developed for use with censored data (Akritas & Siebert 1996). Partial correlation analyses confirm previous findings (e.g., Avni et al. 1995; VBS03): α_{ox} depends primarily upon rest-frame 2500 Å luminosity. The significance of this anticorrelation is 3.5–4.0 σ (slightly higher than in

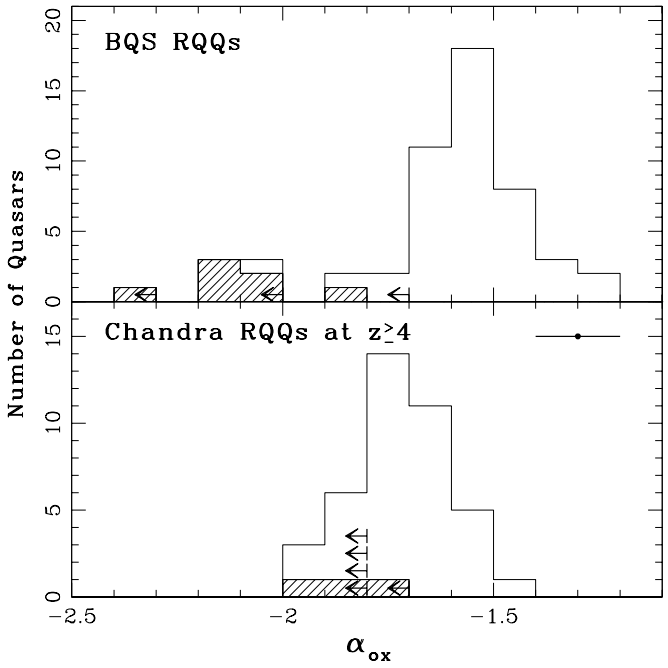

FIG. 6.—α_{ox} distributions for the BQS RQQs observed by *ROSAT* (*top*) and $z \geq 4$ RQQs observed by *Chandra* (*bottom*). The shaded areas indicate the BALQSOs or mini-BALQSOs; the areas with arrows indicate 95% confidence upper limits. The average uncertainty in the α_{ox} measurements from the *Chandra* observations is shown in the bottom panel as the error bar near the top right.

[12] This average value is flatter by 0.04 than that originally reported in V03 because of the flux correction discussed in § 3.

[13] This is an updated version of equation (2) of VBS03, taking into account the correction for the quantum efficiency decay of ACIS.

[14] See § 2.2 of VBS03 for discussion about the method used to derive 2500 Å fluxes from the SDSS filters.

NOTES.—The luminosities are in the quasars' rest frames and have been obtained (or converted) adopting $H_0 = 70$ km s^{-1} Mpc^{-1} in a Λ-cosmology with $\Omega_M = 0.3$ and $\Omega_\Lambda = 0.7$. $l_{2500\text{Å}}$ is in units of ergs s^{-1} Hz^{-1} and $L_{2-10\text{keV}}$ is in units of ergs s^{-1}. Corrections for the *Chandra* ACIS quantum efficiency decay at low energies have been applied in the computation of the X-ray luminosities and $\alpha_{\rm ox}$ values (see § 3 for details). BALQSOs and mini-BALQSOs have been excluded from all of the samples used here. For the SDSS and PSS+BRI samples at $z \geq 4$, the values presented here have been obtained using *Chandra* and *XMM-Newton* results. For the BQS sample, the rest-frame 2–10 keV luminosities have been obtained from a representative subsample of 21 BQS RQQs observed by *ASCA* (George et al. 2000) and *BeppoSAX* (Mineo et al. 2000) in the observed $\approx$0.5–10 keV and $\approx$0.1–10 keV bands, respectively. This subsample covers approximately the same range in redshift as the original sample of 46 BQS RQQs with $M_B < -23$ used in § 3.1.1 of Brandt et al. (2001).

[a] The errors on average values represent the standard deviation of the mean.

[b] $\alpha_{\rm ox} = -2.06$ represents the slope of PG 2214+139. See Appendix A of Laor & Brandt (2002) for a discussion about possible absorption in this quasar.

REFERENCES.—(1) Brandt et al. 2000; (2) George et al. 2000; (3) Mineo et al. 2000; (4) Brandt et al. 2001; (5) V01a; (6) Brandt et al. 2002; (7) Bechtold et al. 2003; (8) this paper; (9) V03.

VBS03), depending upon whether PSS/BRI quasars and BALQSOs are included in the analyses (see Table 5). No significant correlation of $\alpha_{\rm ox}$ with redshift is found. These results suggest that the mechanism driving quasar broad-band emission is similar in the local and early universe, with no evidence for unusual phenomena in high-redshift quasar nuclei such as "trapping radius" effects (e.g., Begelman 1979) or accretion disk instabilities (e.g., Lightman & Eardley 1974).

Although we did not find a significant correlation of $\alpha_{\rm ox}$ with either rest-frame 2500 Å luminosity or redshift using only the $z \geq 4$ RQQs, the spread of $\alpha_{\rm ox}$ for $z \geq 4$ RQQs is unlikely to be explained solely by measurement errors. To demonstrate this, we have applied the likelihood method described in § IV of Maccacaro et al. (1988) to calculate the intrinsic dispersion of $\alpha_{\rm ox}$ (accounting for measurement errors). Ignoring upper limits, we find an intrinsic dispersion of $\sigma_i = 0.062^{+0.030}_{-0.033}$ (68% confidence errors for two interesting parameters; see Maccacaro et al. 1988). Accounting for upper limits would only increase the intrinsic dispersion (see Fig. 6, *bottom*). For comparison, the "straight" dispersion (not accounting for measurement errors) is $\sigma_s = 0.110$.

SDSS 0231−0728 and RD 657 have the flattest $\alpha_{\rm ox}$ values in our sample. It is possible (see § 4) that they experienced variability over the period between the optical and X-ray observations. An alternative explanation could be the presence of some dust obscuring the optical/ultraviolet radiation but not the X-ray emission. The optical spectra of these quasars, however, do not show any clear evidence supporting this scenario. Radio emission can affect the

TABLE 5
DEPENDENCIES OF $\alpha_{\rm ox}$ UPON REDSHIFT AND 2500 Å LUMINOSITY DENSITY FROM PARTIAL CORRELATION ANALYSIS

Sample Name	Number of RQQs	$\alpha_{\rm ox}$-z	$\alpha_{\rm ox}$–$\log l_{2500\text{Å}}$
SDSS only, with BALQSOs	148	$1.2\,\sigma$	$3.7\,\sigma$
SDSS only, without BALQSOs	138	$0.9\,\sigma$	$3.5\,\sigma$
SDSS + PSS, with BALQSOs	163	$1.3\,\sigma$	$3.9\,\sigma$

SDSS + PSS + BRI, with BALQSOs	170	$1.4\,\sigma$	$4.0\,\sigma$
SDSS + PSS + BRI, without BALQSOs	159	$1.1\,\sigma$	$4.0\,\sigma$

quasar broadband spectral energy distributions producing flatter α_{ox} values. Although significant radio emission can be ruled out for SDSS 0231−0728 (see Table 3), the radio-loudness upper limit for RD 657 is not sufficiently tight to exclude some radio emission from this quasar.

SDSS 0913+5919, the only radio-loud object in our sample and the highest redshift RLQ with an X-ray detection, has the highest R parameter ($R \approx 411$) and the steepest α_{ox} (-1.67 ± 0.11) among the RLQs observed thus far by *Chandra* at $z > 4$ (V01a; V03). X-ray absorption might be an explanation for the steep α_{ox} value, although the detection of five of the six source counts in the soft band (see Table 2) suggests a different interpretation. The anticorrelation between α_{ox} and rest-frame 2500 Å luminosity (e.g., Avni et al. 1995; VBS03) cannot explain its steep (for a RLQ) α_{ox} value, since SDSS 0913+5919 is also the optically faintest $z > 4$ RLQ observed by *Chandra* to date.

4.3. *Joint X-Ray Spectral Fitting of SDSS Quasars at $z > 4.8$*

To define the average X-ray spectral properties of high-redshift SDSS quasars and to make a comparison with those obtained for a sample of nine optically luminous PSS quasars at $z \approx 4.1$–4.5 (V03), we have selected a sample of 13 SDSS quasars at $z > 4.8$ detected by *Chandra* ($\langle z \rangle = 5.23$). Their total exposure time is 81.6 ks. The quasars in this sample are selected to have more than two counts in the full band; this choice excludes SDSS 0756+4502 (presented in this paper) and SDSS 1208+0010 (V01a).

Five of the quasars used in this sample have been previously published: the three highest redshift SDSS quasars observed thus far (SDSS 1030+0524, SDSS 1306+0356, and SDSS 0836+0054; Brandt et al. 2002), SDSS 1204−0021 (Bechtold et al. 2003), and SDSS 0211−0009 (V01a). Eleven of the 13 quasars are radio-quiet; the exceptions are SDSS 0836+0054 (radio-moderate with $R \approx 10$) and SDSS 0913+5919 (radio-loud with $R \approx 411$; see Table 3). In the following, we present the joint X-ray spectral analysis both with and without RLQs, since RLQs often appear to be characterized by flatter X-ray photon indices (e.g., Cappi et al. 1997). The sample does not appear to be biased by the presence of a few high signal-to-noise ratio objects. For example, the removal of the radio-moderate quasar SDSS 0836+0054, the second brightest source in the present sample, does not provide significantly different results (see below).

Source counts were extracted from 2″ radius circular apertures centered on the X-ray position of each quasar. The background was taken from annuli centered on the quasars, avoiding the presence of nearby X-ray sources. In total, we have 120 counts (in the rest-frame ≈2.5–36 keV band) from the source extraction regions and five counts from the background regions normalized to the size of those used for the sources; half of the background counts are from the SDSS 0941+5947 field (see § 2.1). All of the ARFs used in the spectral analysis have been corrected to account for the low-energy quantum efficiency decay of ACIS (see § 2.1). As in § 2.1, spectral analysis was carried out with XSPEC using the background-subtracted data and C-statistic (Cash 1979). Since C-statistic fitting is performed using the unbinned data, it retains all the spectral information and allows one to associate with each quasar its own Galactic absorption column density and redshift (for the fitting with intrinsic absorption).

Joint spectral fitting with a power-law model (leaving the normalizations free to vary) and Galactic absorption provides a good fit to the data as judged by the small data-to-model residuals and checked with 10,000 Monte Carlo simulations. The resulting photon index is $\Gamma = 1.84^{+0.31}_{-0.30}$. Excluding the two non-RQQs from the joint spectral fitting gives a similar result ($\Gamma = 1.86^{+0.41}_{-0.37}$). These photon indices are consistent with those obtained for $z \approx 0$–3 samples of RQQs in the rest-frame 2–10 keV band (e.g., George et al. 2000; Mineo et al. 2000; Reeves & Turner 2000; Page et al. 2003) and the $z \approx 4.1$–4.5 optically luminous PSS quasars presented in V03 ($\Gamma = 1.98 \pm 0.16$). As a consistency check, we compared the photon index obtained from joint spectral fitting with that derived from band-ratio analysis (i.e., the ratio of the 2–8 keV to 0.5–2 keV counts; we have assumed for the Galactic column density the average value for the 13 quasars weighted by their number of counts). In this case, we obtain $\Gamma = 1.85^{+0.22}_{-0.20}$.[15]

We also constrained the presence of neutral intrinsic absorption; the joint-fitting technique described above provides a counts-weighted average column density. Solar abundances have been assumed, although previous optical studies indicate that high-redshift quasar nuclei are often characterized by supersolar abundances of heavy elements (e.g., Hamann & Ferland 1999; Constantin et al. 2002; Dietrich et al. 2003). Doubling the abundances in the fit gives a reduction in the column density of a factor of ≈2. No evidence for absorption in excess of the Galactic column density has been found, as shown by the 68%, 90%, and 99% confidence regions plotted in Figure 7. On average, it appears that any neutral X-ray absorption in $z > 4.8$ X-ray–detected SDSS quasars has a column density of $N_H < 3.95 \times 10^{22}$ cm^{-2} (at the 90% confidence level; $N_H < 4.37 \times 10^{22}$ cm^{-2} when only the RQQs are used in the spectral analysis). For comparison, X-ray absorption of $\approx(2\text{–}5) \times 10^{22}$ cm^{-2} has been detected in a few RQQs and some RLQs at $z \approx 1$–3 (e.g., Cappi et al. 1997; Reeves & Turner 2000). Given the limited counting statistics available for the present sample, it is not possible to obtain useful spectral constraints for more complex absorption models (e.g., ionized absorption). The typical upper limits on the equivalent widths of narrow iron Kα lines (either neutral or ionized) are in the range 420–950 eV.

The X-ray spectral results at $z > 4$ presented here and in V03 allow us to place constraints on any spectral changes in the X-ray continua of RQQs as a function of redshift. In Figure 8, we plot the photon index as a function of redshift for some optically selected samples of RQQs. The photon indices plotted in the figure are for the nuclear, high-energy ($\gtrsim 2$ keV) component, in order to avoid spectral complexities such as soft excesses. The *ASCA* RQQs have been taken from Vignali et al. (1999, V99 in the key), George et al. (2000, G00), Reeves & Turner (2000, RT00), and Vignali et al. (2001b, V01b). The *BeppoSAX* RQQs are from Mineo et al. (2000, M00). At the highest redshifts, we plot the $z = 3.91$ gravitationally lensed BALQSO APM 08279+5255 (Chartas et al. 2002; C02), the results obtained from joint X-ray spectral fitting of nine PSS quasars in the

[15] If we increase the number of soft-band counts by 10% to take into account crudely the quantum efficiency decay of ACIS at soft energies, we obtain $\Gamma = 1.93^{+0.21}_{-0.20}$. The small differences in the photon indices obtained via joint spectral fitting and band-ratio analysis (with a 10% increment in the number of soft-band counts) are probably due to the fact that only the former retains all the spectral information.

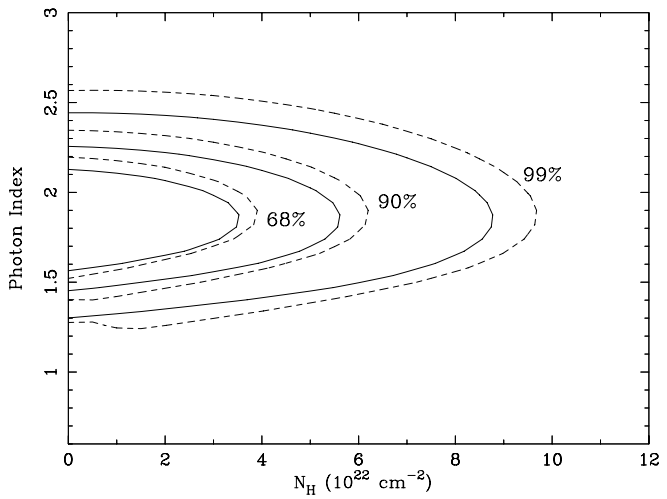

FIG. 7.—Confidence regions for the photon index and intrinsic column density derived from joint spectral fitting of the 13 SDSS quasars (11 RQQs, two non-RQQs) at $z > 4.8$ thus far detected by *Chandra* with more than two full-band counts (*solid contours*; see § 4.3 for details). Dashed contours indicate the results obtained when only the 11 SDSS RQQs at $z > 4.8$ are considered in the joint spectral fitting.

redshift range $z \approx 4.1$–4.5 (V03) and the 11 SDSS RQQs at $z > 4.8$ presented in this paper. The distribution of X-ray photon indices is characterized by significant scatter, so precise parametric modeling of any Γ versus redshift relation is difficult. However, according to a Spearman's ρ correlation test, a correlation between Γ and redshift is not significant ($2.3\,\sigma$). Applying a linear regression algorithm that accounts for intrinsic scatter and measurement errors (Akritas & Bershady 1996), we obtain $|\,\partial\Gamma/\partial z\,| < 0.05 \pm 0.03$.

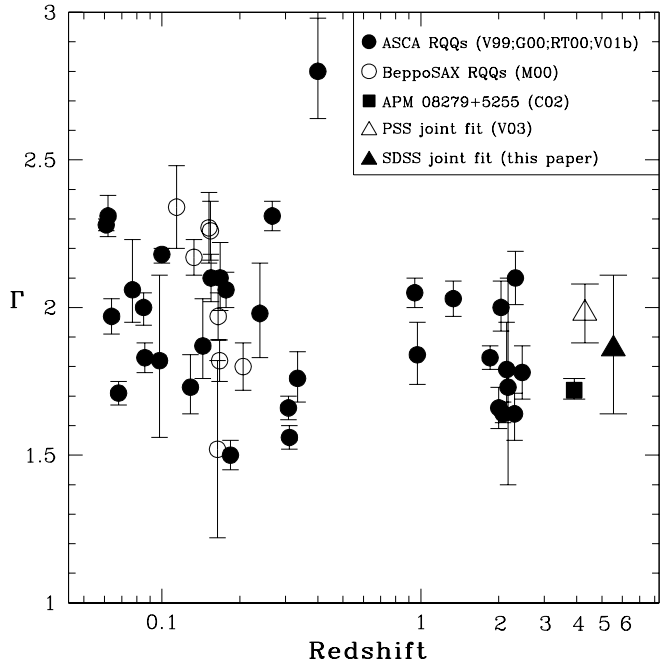

FIG. 8.—Plot of photon index vs. redshift for optically selected RQQs. The *ASCA* RQQs have been taken from Vignali et al. (1999; V99 in the key), George et al. (2000; G00), Reeves & Turner (2000; RT00), and Vignali et al. (2001b; V01b). The *BeppoSAX* RQQs are from Mineo et al. (2000; M00). At the highest redshifts, we plot the $z = 3.91$ gravitationally lensed BALQSO APM 08279+5255 (Chartas et al. 2002; C02), the results obtained from joint X-ray spectral fitting of nine PSS quasars in the redshift range $z \approx 4.1$–4.5 (V03), and the 11 SDSS RQQs at $z > 4.8$ presented in this paper (the latter two data points are plotted at the average redshifts of the relevant papers). Error bars are at the 68% confidence level for all data points. The object with the steepest X-ray photon index in this plot, PG 1543+489 (George et al. 2000), is known to be a narrow-line type 1 quasar (Boroson & Green 1992).

5. SUMMARY

We have reported the *Chandra* and *XMM-Newton* observations of a sample of 13 quasars at $z \approx 4.7$–5.4, the majority of them selected by the SDSS and compared their properties with those of all the $z \geq 4$ quasars previously observed in the X-ray band. The principal results are the following:

1. Eleven quasars have been detected in the X-ray band, doubling the number of $z \geq 4.8$ X-ray–detected quasars. The X-ray detections include SDSS 0913+5919, the highest redshift ($z = 5.11$) RLQ thus far detected in the X-ray band. Two quasars, SDSS 0338+0021 and SDSS 1737+5828, were not detected by the present observations. The former nondetection is probably due to the short exposure time of the *XMM-Newton* observation after removal of flaring-background intervals. For the latter quasar, strong X-ray absorption ($N_{\rm H} \gtrsim 1.2 \times 10^{23}$ cm^{-2} at the source redshift) is a likely explanation. An HET spectrum of this source, revealing absorption features, seems to support this hypothesis. For our sample, no evidence for source extension or an overdensity of companion objects has been found.

2. The presence of a significant correlation between the soft X-ray flux and $AB_{1450(1+z)}$ magnitude has been extended to the highest redshifts. This indicates that the same engine (namely accretion onto a supermassive black hole) is powering the ultraviolet and X-ray emission.

3. The anticorrelation between $\alpha_{\rm ox}$ and rest-frame 2500 Å luminosity density found for SDSS RQQs over the redshift range $z \approx 0.2$–6.3 (VBS03) has been confirmed (3.5–4.0 σ significance level) after the inclusion of the RQQs presented in this paper. Similarly to VBS03, no significant correlation between $\alpha_{\rm ox}$ and redshift has been found. These results suggest that the mechanism driving quasar broadband emission is similar in the local and early universe, with no evidence for unusual phenomena in high-redshift quasar nuclei such as "trapping radius" effects or accretion disk instabilities.

4. The joint ≈2.5–36 keV rest-frame X-ray spectrum of the 13 SDSS quasars at $z > 4.8$ observed thus far by *Chandra* is well parameterized by a simple power-law model with $\Gamma = 1.84^{+0.31}_{-0.30}$ and no evidence for intrinsic absorption ($N_{\rm H} \lesssim 4.0 \times 10^{22}$cm^{-2} at 90% confidence).

5. There is no evidence for significant (greater than 30%) optical variability over the time interval of a few years (in the observed frame) between the SDSS and HET observations.

Among the quasars presented in this paper, the only object suitable for moderate-quality (≈1000 photons) X-ray spectroscopy in a 50 ks *XMM-Newton* observation is SDSS 0231−0728. X-ray spectroscopy of the other quasars will be possible only with future missions such as Constellation-X, *XEUS*, and *Generation-X* (see V03 for some relevant simulations).

Brunetti and G. Chartas for useful discussions, S. Djorgovski for providing us with the results on RD 657 before their publication, G. Garmire for discussions about ACIS quantum efficiency decay, and L. Ramsey for kindly allocating the time for the HET spectroscopic observation presented here. The HET is a joint project of the University of Texas at Austin, Pennsylvania State University, Stanford University, Ludwig-Maximillians-Universität München, and Georg-August-Universität Göttingen. The HET is named in honor of its principal benefactors, William P. Hobby and Robert E. Eberly. The Marcario Low-Resolution Spectrograph is named for Mike Marcario of High Lonesome Optics, who fabricated several optics for the instrument but died before its completion; it is a joint project of the HET partnership and the Instituto de Astronomía de la Universidad Nacional Autónoma de México. Funding for the creation and distribution of the SDSS Archive has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Aeronautics and Space Administration, the National Science Foundation, the US Department of Energy, the Japanese Monbukagakusho, and the Max Planck Society. The SDSS Web site is http://www.sdss.org/. The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions. The Participating Institutions are the University of Chicago, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, Los Alamos National Laboratory, the Max-Planck-Institut für Astronomie, the Max-Planck-Institut für Astrophysik, New Mexico State University, the University of Pittsburgh, Princeton University, the US Naval Observatory, and the University of Washington.

APPENDIX

In Table A1, we report the updated X-ray flux values (and derived quantities) for $z \geq 4$ quasars observed by *Chandra* in the past. The X-ray values have been corrected for the ACIS quantum energy decay at low energies.

TABLE A1

OPTICAL, X-RAY, AND RADIO PROPERTIES OF $z \geq 4$ QUASARS PREVIOUSLY OBSERVED BY *Chandra*

Object	z	$AB_{1450(1+z)}$	$f_{2500Å}$	log ($L_{2500Å}$)[a]	M_B	$f_{0.5-2keV}$	f_{2keV}	log (L_{2keV})[b]	log ($L_{2-10keV}$)	α_{ox}	R
