### ABSTRACT

We use spectroscopic observations of a sample of 82 H II regions in 76 blue compact galaxies to determine the primordial helium abundance  $Y_p$  and the slope  $dY/dZ$  from the Y-O/H linear regression. To improve the accuracy of the  $dY/dZ$  measurement, we have included new spectrophotometric observations of 33 H II regions that span a large metallicity range, with oxygen abundance  $12 + \log(\text{O}/\text{H})$  varying between 7.43 and 8.30 ( $Z_{\odot}/30 \leq Z \leq Z_{\odot}/4$ ). Most of the new galaxies were selected from the First Byurakan, the Hamburg/SAO, and the University of Michigan objective prism surveys. For a subsample of seven H II regions, we derive the He mass fraction taking into account known systematic effects, including collisional and fluorescent enhancements of He I emission lines, collisional excitation of hydrogen emission, underlying stellar He I absorption, and the difference between the temperatures  $T_e(\text{He II})$  in the He<sup>+</sup> zone and  $T_e(\text{O III})$  derived from the collisionally excited [O III] lines. We find that the net result of all the systematic effects combined is small, changing the He mass fraction by less than 0.6%. By extrapolating the Y versus O/H linear regression to O/H = 0 for seven H II regions of this subsample, we obtain  $Y_p = 0.2421 \pm 0.0021$  and  $dY/dO = 5.7 \pm 1.8$ , which corresponds to  $dY/dZ = 3.7 \pm 1.2$ , assuming the oxygen mass fraction to be  $O = 0.66Z$ . In the framework of the standard big bang nucleosynthesis theory, this  $Y_p$  corresponds to  $\Omega_b h^2 = 0.012^{+0.003}_{-0.002}$ , where  $h$  is the Hubble constant in units of  $100 \text{ km s}^{-1} \text{ Mpc}^{-1}$ . This is smaller at the  $2\sigma$  level than the value obtained from recent deuterium abundance and microwave background radiation measurements. The linear regression slope  $dY/dO = 4.3 \pm 0.7$  (corresponding to  $dY/dZ = 2.8 \pm 0.5$ ) for the whole sample of 82 H II regions is similar to that derived for the subsample of seven H II regions, although it has a considerably smaller uncertainty.

### 1. INTRODUCTION

It is now well established that four light isotopes, D,  ${}^3\text{He}$ ,  ${}^4\text{He}$ , and  ${}^7\text{Li}$ , were produced by nuclear reactions within the first few minutes after the birth of the universe (Reeves 1994; Wilson & Rood 1994; Sarkar 1996; Tytler et al. 2000). In the standard theory of big bang nucleosynthesis (SBBN), given the number of light neutrino species  $N_{\nu} = 3$ , the abundances of these light elements depend on one cosmological parameter only, the baryon-to-photon number ratio  $\eta$ , which in turn is directly related to the density of ordinary baryonic matter  $\Omega_b h^2$  (Walker et al. 1991), where  $h$  is the Hubble constant in units of  $100 \text{ km s}^{-1} \text{ Mpc}^{-1}$ . Thus, precise abundance measurements of the four light elements can provide not only a stringent test of the consistency of SBBN but also information about the mean density of ordinary matter in the universe.

Deuterium is the best element for deriving the baryonic mass fraction because its abundance is strongly dependent on  $\eta$ . Much progress has been achieved during the last years in the precise measurement of the deuterium abundance

in high-redshift, low-metallicity Ly $\alpha$  absorption systems (Burles & Tytler 1998a, 1998b; O'Meara et al. 2001; Pettini & Bowen 2001; Kirkman et al. 2003). These measurements appear to converge to the mean value  $D/\text{H} \sim 3 \times 10^{-5}$ , which corresponds to  $\Omega_b h^2 \sim 0.020 \pm 0.002$ . This value is in good agreement with the ones of 0.021–0.022 from recent studies of the fluctuations of the cosmic microwave background (CMB; Pryke et al. 2002; Netterfield et al. 2002; Spergel et al. 2003).

Determining the primordial abundance of  ${}^3\text{He}$  is more difficult. Not only is it destroyed in stars, but it can also be produced by low-mass stars. Thus, the derivation of its primordial value is complicated by our lack of understanding of both the chemical evolution of the Galaxy and the production of  ${}^3\text{He}$  in stars. However, recently Bania, Rood, & Balser (2002) determined an upper limit for the primordial abundance of  ${}^3\text{He}$  relative to hydrogen  ${}^3\text{He}/\text{H} = (1.1 \pm 0.2) \times 10^{-5}$  by arguing that most solar-mass stars do not produce enough  ${}^3\text{He}$  to enrich the interstellar medium significantly. This corresponds to  $\Omega_b h^2 \sim 0.020^{+0.007}_{-0.003}$ , in excellent agreement with the value obtained from the deuterium and CMB measurements.

As for the primordial abundance of  ${}^7\text{Li}$ , possible correlations of its value with temperature and metallicity in old hot Population II stars may introduce systematic errors. The value

<sup>1</sup> Visiting Astronomer, Kitt Peak National Observatory, National Optical Astronomical Observatory, operated by the Association of Universities for Research in Astronomy, Inc., under contract with the National Science Foundation.

for the  $^7\text{Li}$  primordial abundance derived from the  $^7\text{Li}$  abundance plateau of halo stars by Bonifacio & Molaro (1997) is  ${}^7\text{Li}/\text{H} = (1.75 \pm 0.05_{\sigma} \pm 0.20_{\text{sys}}) \times 10^{-10}$ , corresponding to two possible values for the baryonic density  $\Omega_b h^2 = 0.006$  and 0.015, below the value derived from the D abundance and CMB measurements. Furthermore, Ryan, Norris, & Beers (1999) found a correlation of the  $^7\text{Li}$  abundance with the metallicity of halo stars and inferred  ${}^7\text{Li}/\text{H} = 1.0 \times 10^{-10}$ , corresponding to a single value of  $\Omega_b h^2 = 0.009$ , while Ryan et al. (2000) find  ${}^7\text{Li}/\text{H} = (1.23^{+0.68}_{-0.32}) \times 10^{-10}$ , significantly below the value of  $(4.5^{+0.9}_{-0.8}) \times 10^{-10}$ , predicted by SBBN from the primordial D abundance (Kirkman et al. 2003). However, recently Ford et al. (2002) have shown that the  $^7\text{Li}$  abundance derived in stars depends on the Li I line used. From the weak Li I  $\lambda 6104$  subordinate line instead of the commonly used Li I  $\lambda 6708$  resonance line, they derived a much higher  ${}^7\text{Li}$  abundance of  $\sim 3 \times 10^{-10}$ , consistent with the SBBN predicted value.

The primordial mass fraction  $Y_p$  of  $^4\text{He}$  can be derived with a much better precision compared to the primordial abundances of other light elements.  $Y_p$  is usually derived by extrapolating the  $Y\text{-O/H}$  and  $Y\text{-N/H}$  correlations to  $\text{O/H} = \text{N/H} = 0$ , as proposed originally by Peimbert & Torres-Peimbert (1974), Peimbert & Torres-Peimbert (1976), and Pagel, Terlevich, & Melnick (1986). Many attempts at determining  $Y_p$  have been made, constructing these correlations for various samples of dwarf irregular and blue compact galaxies (BCGs; see references in Izotov & Thuan 1998b, hereafter IT98b). These dwarf systems are the least chemically evolved galaxies known, so they contain very little helium manufactured by stars after the big bang, allowing us to bypass the chemical evolution problems that plague the determination of  ${}^3\text{He}$ . However, because the big bang production of  ${}^4\text{He}$  is relatively insensitive to the density of baryonic matter, the primordial abundance of  ${}^4\text{He}$  needs to be determined to a very high precision (to better than 1%) in order to put useful constraints on  $\Omega_b$  and  $N_{\nu}$ . Uncertainties in the determination of  $Y_p$  can be statistical or systematic. Statistical uncertainties can be decreased by obtaining very high signal-to-noise ratio spectra of BCGs. These BCGs are undergoing intense bursts of star formation, giving birth to high-excitation supergiant H II regions and allowing an accurate determination of the helium abundance in the ionized gas through the BCG emission-line spectra. The theory of nebular emission is well understood enough not to introduce additional uncertainty.

Care should also be exercised to consider all possible systematic effects. We have considered several systematic effects in our previous primordial helium work. First, we have solved consistently for the electron density  $N_e(\text{He II})$  in the He<sup>+</sup> zone rather than just setting it to  $N_e(\text{S II})$  as was done by previous investigators. Second, we have corrected the He I emission lines for collisional and fluorescent enhancements. With those systematic effects taken into account, Izotov, Thuan, & Lipovetsky (1997, hereafter ITL97b), by fitting linear regression lines to the  $Y\text{-O/H}$  and  $Y\text{-N/H}$  correlations for a sample of 23 BCGs, have derived  $Y_p = 0.243 \pm 0.003$ . IT98b, by extending that sample to 45 H II regions in 41 BCGs, have obtained  $0.244 \pm 0.002$ . These values are significantly higher than those of  $0.228\text{--}0.234$  obtained by Pagel et al. (1992) and Olive, Skillman, & Steigman (1997) with lower signal-to-noise ratio spectra, by setting  $N_e(\text{He II}) = N_e(\text{S II})$  and not taking into account fluorescent enhancements of the He I lines.

We have also determined  $Y$  in individual very metal-deficient BCGs. Izotov et al. (1999) have derived the helium

abundance in I Zw 18 ( $Z_{\odot}/50$ ), Izotov et al. (1997a) in SBS 0335–052 ( $Z_{\odot}/40$ ), Guseva et al. (2001) in SBS 0940+544 ( $Z_{\odot}/29$ ), Izotov, Chaffee, & Green (2001a) in Tol 1214–277 ( $Z_{\odot}/24$ ) and Tol 65 ( $Z_{\odot}/24$ ), and Thuan, Izotov, & Foltz (1999) in SBS 1415+437 ( $Z_{\odot}/21$ ), using high signal-to-noise ratio spectra obtained with the MMT and the Keck telescope. Except for I Zw 18, these determinations have all resulted in a  ${}^4\text{He}$  mass fraction in the narrow range  $Y = 0.245\text{--}0.246$ . The helium mass fraction for the southeastern component of I Zw 18,  $Y = 0.243$ , is lower because of the contribution of underlying stellar He I absorption (Izotov & Thuan 1998a; Izotov et al. 1999). Using the two most metal-deficient BCGs known, I Zw 18 and SBS 0335–052, Izotov et al. (1999) derived a primordial helium mass fraction  $Y_p = 0.245 \pm 0.002$ .

However, there are other systematic effects that may either increase or decrease  $Y_p$  that were not taken into account in our previous work. First, there is the possible systematic effect of underlying He I stellar absorption (ITL97b; IT98b). Correction for this increases  $Y$  in the galaxy. In particular, He I stellar absorption is important in I Zw 18 (Izotov & Thuan 1998a; Izotov et al. 1999). Because it has the lowest metallicity known, I Zw 18 plays an important role in the determination of  $Y_p$ . The lower  $Y_p$  derived by other groups (Pagel et al. 1992; Olive et al. 1997) is largely the result of neglecting underlying He I stellar absorption in I Zw 18. A second possible systematic effect is the collisional excitation of hydrogen lines (Stasińska & Izotov 2001; Peimbert, Peimbert, & Luridiana 2002). Correction for this effect also increases  $Y$ . The third systematic effect concerns the temperature structure of the H II region. The electron temperature of the He<sup>+</sup> zone  $T_e(\text{He II})$  is usually set equal to the temperature  $T_e(\text{O III})$  derived from the collisionally excited [O III] emission lines. Recent work has shown that  $T_e(\text{He II})$  may be smaller than  $T_e(\text{O III})$  (Peimbert, Peimbert, & Ruiz 2000; Peimbert et al. 2002; Sauer & Jedamzik 2002). Correction for this effect decreases  $Y$ . A last systematic effect concerns the ionization structure of the H II region. The He<sup>+</sup> zone can be larger or smaller than the H<sup>+</sup> zone. Therefore, an ionization correction factor ICF(He) should be applied. In high-excitation, low-metallicity H II regions, the ionization correction factor ICF(He) may be slightly higher or lower than unity (Viegas, Gruenwald, & Steigman 2000; Izotov et al. 2001a; Gruenwald, Steigman, & Viegas 2002; Peimbert et al. 2002; Sauer & Jedamzik 2002). These different systematic effects work in opposite directions, and it is a priori not clear whether combining all of them would increase or decrease  $Y_p$ . Preliminary estimates by Thuan & Izotov (2002) suggest that, after correction for all the systematic effects mentioned above,  $Y_p$  may increase by as much as  $\sim 2\text{--}4\%$ .

Besides the  $Y_p$  problem, there is also a need to improve the accuracy of the determination of the slope  $dY/dZ$  from the  $Y\text{-O/H}$  linear regression. ITL97b and IT98b have derived  $dY/dZ = 1.7 \pm 0.9$  and  $2.4 \pm 1.0$ , respectively. These values are in agreement, within the errors, with the slope  $dY/dZ = 2.1 \pm 0.4$  derived by Jimenez et al. (2003) using K dwarf stars with accurate spectroscopic metallicities in the *Hipparcos* catalog and with the slope  $dY/dZ = 1.5 \pm 0.3$  derived by Peimbert (2003) from observations of two relatively metal-rich H II regions, 30 Dor and NGC 346. They are also in agreement with the values predicted by chemical evolution models of dwarf galaxies (Carigi et al. 1995; Carigi, Colín, & Peimbert 1999), although the errors on  $dY/dZ$  are still large and do not allow us to strongly constrain these models. The reason for this state of affairs is that, for the  $Y_p$  problem, attention has been

paid mainly to very low metallicity BCGs. For example, the sample of IT98b contains very few intermediate-metallicity BCGs.

We address the two problems of systematic effects on the determination of  $Y_p$  and of improving the accuracy of  $dY/dZ$  in this paper. To obtain a more accurate  $dY/dZ$ , we have added to our sample 31 new BCGs spanning a considerably wider range of oxygen abundance, resulting in a total sample of 76 BCGs with 82 H II regions. To take into account systematic effects on the determination of  $Y_p$ , we have studied them in detail in a subsample of seven H II regions.

We describe the sample, observations, and data reduction in § 2. In § 3 we determine the physical conditions and heavy-element abundances for all 82 H II regions in the total sample. Helium abundances are derived in § 4. In § 5 we present our new best values for  $Y_p$  and for the linear regression slope  $dY/dZ$ , which has considerably reduced errors. In §§ 3, 4, and 5, to compare the  $Y_p$  derived from our new increased sample of 82 H II regions with our previous  $Y_p$  determinations from smaller samples (ITL97b, IT98b), we have proceeded in the same manner as in our previous work concerning systematic effects. We have determined self-consistently  $N_e(\text{He II})$  and corrected the He I line fluxes for collisional and fluorescent enhancements. To estimate the net change incurred by  $Y_p$  if all known systematic effects are taken into account, we have analyzed a restricted subsample of seven H II regions. We present our best value of  $Y_p$  and  $dY/dZ$  corrected for systematic effects in § 6. The implications of our results on cosmology are discussed in § 7. We summarize our conclusions in § 8.

## 2. OBSERVATIONS AND DATA REDUCTION

We have obtained new high signal-to-noise ratio spectro-photometric observations for 33 H II regions in 31 BCGs with the Kitt Peak 4 m telescope on the nights of 2002 December 30–31 and 2003 January 1. The majority of the galaxies were selected from the First Byurakan (Markarian; Markarian 1967), the University of Michigan (Salzer & MacAlpine 1988), and Hamburg/SAO (Ugryumov et al. 1999) objective prism surveys. In choosing the candidates, we have used two main selection criteria. First, they need to have high equivalent widths (EWs) of the H $\beta$  emission line [in general,  $\text{EW}(\text{H}\beta) > 200 \text{ \AA}$ ] to minimize the influence of underlying He absorption on the He abundance determination. Second, they are to span a wide range of metallicities, from  $\sim Z_\odot/50$  to  $\sim Z_\odot/3$ , so as to allow an improved determination of  $dY/dZ$ . The observed galaxies are listed in Table 1 in order of increasing right ascension, along with some of their general properties such as coordinates, apparent magnitudes, redshifts, and absolute magnitudes. Relevant references are also given.

All observations were made with the Ritchey-Chrétien spectrograph used in conjunction with the  $2048 \times 2048$  CCD detector. We use a  $2'' \times 300''$  slit with the grating KPC-10A in first order and with a GG 375 order separation filter. This filter cuts off all second-order contamination for wavelengths blueward of  $7400 \text{ \AA}$ , which is the wavelength region of interest here. The above instrumental setup gave a spatial scale along the slit of  $0''.69 \text{ pixel}^{-1}$ , a scale perpendicular to the slit of  $2.7 \text{ \AA pixel}^{-1}$ , a spectral range of  $3500\text{--}7500 \text{ \AA}$ , and a spectral resolution of  $\sim 7 \text{ \AA}$  (FWHM). These parameters permitted us to cover simultaneously the blue and red spectral

range with all the lines of interest in a single exposure and with enough spectral resolution to separate important emission lines as H $\gamma \lambda 4340$  and [O III]  $\lambda 4363$ , as well as H $\alpha \lambda 6563$  and [N II]  $\lambda 6584$ . The seeing was in the range  $1''\text{--}2''$ . Total exposure times varied between 20 and 60 minutes. Each exposure was broken up into two to four subexposures, not exceeding 20 minutes, to allow for removal of cosmic rays. Three Kitt Peak IRS spectroscopic standard stars, Feige 110, Feige 34, and HZ 44, were observed at the beginning, middle, and end of each night for flux calibration. Spectra of He-Ne-Ar comparison arcs were obtained before or after each observation to calibrate the wavelength scale. The log of the observations is given in Table 2.

The two-dimensional spectra were bias subtracted and flat-field corrected using IRAF.<sup>2</sup> We then use the IRAF software routines IDENTIFY, REIDENTIFY, FITCOORD, and TRANSFORM to perform wavelength calibration and correct for distortion and tilt for each frame. One-dimensional spectra were then extracted from each frame using the APALL routine. Before extraction, distinct two-dimensional spectra of the same H II region were carefully aligned using the spatial locations of the brightest part in each spectrum, so that spectra were extracted at the same positions in all sub-exposures. For all objects we extracted the brightest part of the BCG, corresponding to a different spatial size for each object. In two BCGs, CGCG 007–025 and Mrk 450, spectra of two different H II regions in the same galaxy were extracted. The extraction apertures of the one-dimensional spectra used for abundance determinations are given in Table 2. These spectra have been corrected for the night-sky absorption bands in the red part using spectra of the standard star Feige 34, which contains no absorption lines in that part of the spectrum. All extracted spectra from the same object were then co-added. To perform the co-adding and removal of the cosmic-ray hits, the IMCOMBINE routine is generally used. However, the use of the IMCOMBINE routine can introduce spurious changes in the line intensities of sharp narrow emission lines when small spatial shifts are still present. In those cases, we have simply summed the individual sub-exposures. Cosmic-ray hits have been manually removed in each individual subexposure. Then spectra obtained from each individual subexposure were checked for cosmic-ray hits at the location of strong emission lines. Fortunately, none of them were found.

Particular attention was paid to the derivation of the sensitivity curve. It is crucial that the latter be obtained with a very high accuracy for a precise primordial helium abundance determination. To derive the sensitivity curve, we have fitted with a high-order polynomial the observed spectral energy distribution of the bright hot white dwarf standard stars Feige 110, Feige 34, and HZ 44. Because the spectra of these stars have only a small number of relatively weak absorption features, their spectral energy distributions are known with very good accuracy (Oke 1990). Moreover, the response function of the CCD detector is smooth, so we could derive a sensitivity curve with a precision better than 1% over the whole optical range, except for the region blueward of [O II]  $\lambda 3727$ , where the sensitivity drops precipitously. The resulting spectra

<sup>2</sup> IRAF is distributed by the National Optical Astronomical Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.

for all 33 H II regions are shown in Figure 1. These spectra have been reduced to zero redshift and corrected for interstellar extinction.

As a whole, the H II regions in our new BCG sample show high-excitation spectra, except for Mrk 1063. Nineteen H II regions have an  $H\beta$  equivalent width greater than 200 Å. The observed line fluxes  $F(\lambda)$  normalized to  $F(H\beta)$  and their errors for the 33 H II regions shown in Figure 1 are given in Table 3. They were measured using the IRAF SPLOT routine. The line flux errors listed include statistical errors derived with SPLOT from non-flux-calibrated spectra, in addition to errors introduced in the standard-star absolute flux calibration, which we set to 1% of the line fluxes. These errors will be later propagated into the calculation of abundance errors. The line fluxes were corrected for both reddening (Whitford 1958) and underlying hydrogen stellar absorption derived simultaneously by an iterative procedure as described in Izotov, Thuan, & Lipovetsky (1994, hereafter ITL94). The corrected line fluxes  $I(\lambda)/I(H\beta)$ , equivalent widths  $EW(\lambda)$ , extinction coefficients  $C(H\beta)$ , and equivalent widths  $EW(\text{abs})$  of the hydrogen ab-

sorption stellar lines are also given in Table 3, along with the uncorrected  $H\beta$  fluxes.

### 3. PHYSICAL CONDITIONS AND DETERMINATION OF HEAVY-ELEMENT ABUNDANCES

To determine element abundances, we follow the procedures of ITL94, ITL97b, and Thuan, Izotov, & Lipovetsky (1995). We adopt a two-zone photoionized H II region model: a high-ionization zone with temperature  $T_e(\text{O III})$ , where O III, Ne III, and Ar IV lines originate, and a low-ionization zone with temperature  $T_e(\text{O II})$ , where O II, N II, S II, and Fe III lines originate. As for the Ar III and S III lines, they originate in the intermediate zone between the high- and low-ionization regions (Garnett 1992). We have derived the chlorine abundance from Cl III emission lines in 22 H II regions. We assume that these lines also originate in the intermediate zone as the ionization potentials of the  $\text{S}^{++}$ ,  $\text{Ar}^{++}$ , and  $\text{Cl}^{++}$  ions are similar. The temperature  $T_e(\text{O III})$  is calculated using the  $[\text{O III}] \lambda 4363/\lambda\lambda(4959+5007)$  ratio. To take into account the electron temperatures for different ions, we have used the H II

<sup>a</sup> Aperture used for extraction of one-dimensional spectra.

<sup>b</sup> Galaxies in which two H II regions are used for abundance determination. The two spectra are extracted within equal apertures.

photoionization models of Stasińska (1990), as fitted by the expressions in ITL94 and ITL97b. The [S II]  $\lambda 6717/\lambda 6731$  ratio is used to determine the electron density  $N_e(\text{S II})$ , the minimum value of which was set to be  $10 \text{ cm}^{-3}$ . Ionic and total heavy-element abundances are derived for the 33 H II regions in the manner described in ITL94 and are given in Table 4 along with the adopted ICFs.

As a result of our sample selection criteria, the oxygen abundances in the newly observed H II regions span a wide range of metallicities, going from  $12 + \log(\text{O/H}) = 7.43$  ( $Z_\odot/30$ , J0519+0007) to  $8.30$  ( $Z_\odot/4$ , Mrk 35) with a large fraction of high-metallicity galaxies. Five galaxies among those observed have  $12 + \log(\text{O/H}) > 8.2$  ( $Z_\odot/5$ ). This large metallicity range is crucial for determining an accurate  $dY/dZ$  slope.

#### 4. HELIUM ABUNDANCE

Because the  $Y_p$ - $\eta$  relation has a very shallow slope,  $Y_p$  has to be determined to better than 1% in order to put interesting constraints on the baryonic mass fraction of the universe. In principle, this high precision can be achieved if care is taken to (1) obtain spectra of low-metallicity H II regions with the very highest signal-to-noise ratio; (2) take into account all physical processes that may make He I line intensities deviate from their recombination values, such as collisional and fluorescence enhancements; (3) use the best possible atomic

data; and (4) take into account systematic effects in the determination of the helium mass fraction, such as underlying stellar absorption and the ionization and temperature structures of the H II region.

In this section, to compare the results from the present enlarged sample with our previous work, we derive  $Y_p$  in the same way as ITL94, ITL97b, and IT98b. We solve self-consistently for  $N_e(\text{He II})$  and the optical depth  $\tau(\lambda 3889)$  in the He I  $\lambda 3889$  emission line but do not consider possible temperature and ionization structures in the H II regions. Thus, we set the temperature in the  $\text{He}^+$  zone to be equal to that derived from the  $[\text{O III}] \lambda 4363/\lambda\lambda(4959+5007)$  flux ratio, i.e.,  $T_e(\text{He II}) = T_e(\text{O III})$ . The case in which  $T_e(\text{He II}) \leq T_e(\text{O III})$  will be discussed in § 6 for a subsample of seven H II regions. The He ICFs are set to 1. We consider collisional and fluorescence enhancement effects but do not take into account other systematic effects such as the collisional excitation of hydrogen lines and underlying He I stellar absorption. These effects will be discussed in § 6 as well.

Because observed He I fluxes deviate from their recombination values, corrections are necessary to take into account the physical mechanisms that modify line fluxes. In the range of high temperatures found in BCGs ( $10^4 \text{ K} \lesssim T_e \lesssim 2 \times 10^4 \text{ K}$ ), the main such physical mechanism is collisional excitation from the metastable  $2^3S$  level of He I. The second physical mechanism to consider is fluorescence enhancement where

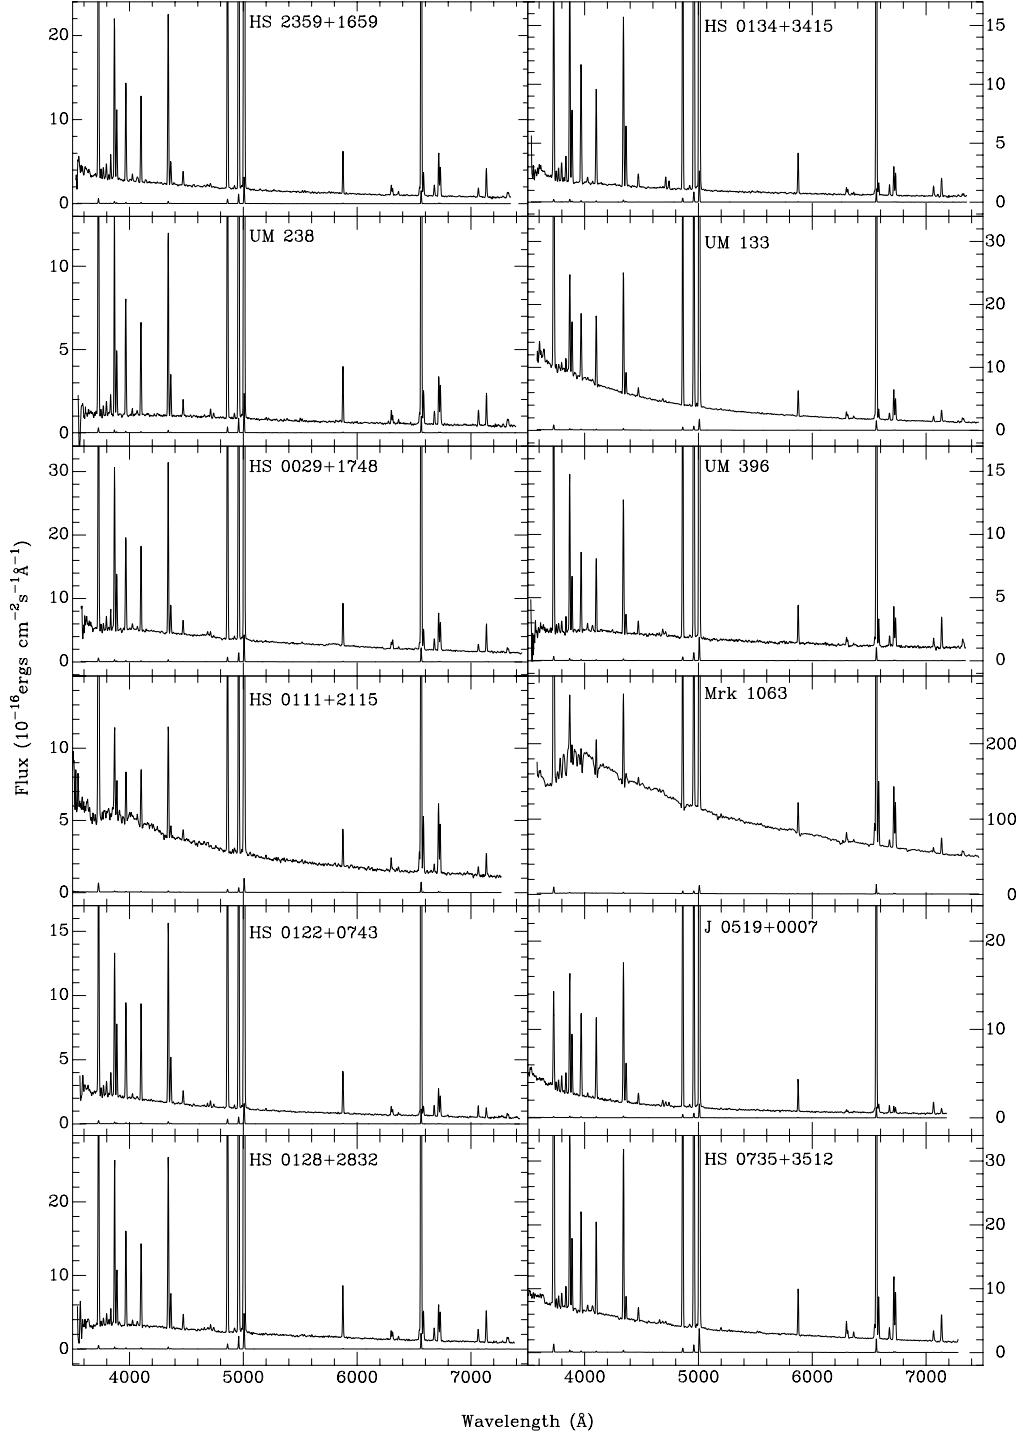

FIG. 1.—Mayall 4 m telescope spectra of 33 H II regions in 31 BCGs

self-absorption in some optically thick emission lines populates the upper levels of He I. To correct line intensities for these effects, we have evaluated the electron number density  $N_e(\text{He II})$  and the optical depth  $\tau(\lambda 3889)$  in the He I  $\lambda 3889$  line in a self-consistent way by minimization of the expression

$$\chi^2 = \sum_i^n \frac{(y_i^+ - y_{\text{mean}}^+)^2}{\sigma^2(y_i^+)}, \quad (1)$$

where  $y_i^+$  is the He $^+$  abundance derived from the flux of the He I emission line with label  $i$ . The quantity  $y_{\text{mean}}^+$  is the

weighted mean of the He $^+$  abundance as derived from the equation

$$y_{\text{mean}}^+ = \frac{\sum_i^k y_i^+ / \sigma^2(y_i^+)}{\sum_i^k 1 / \sigma^2(y_i^+)}. \quad (2)$$

The numbers of lines  $n$  and  $k$  used for the minimization and determination of the weighted mean can be different, and in general  $n \geq k$ .

In this paper, following ITL94, ITL97b, and IT98b, we use the five strongest He I  $\lambda\lambda 3889, 4471, 5876, 6678$ , and 7065

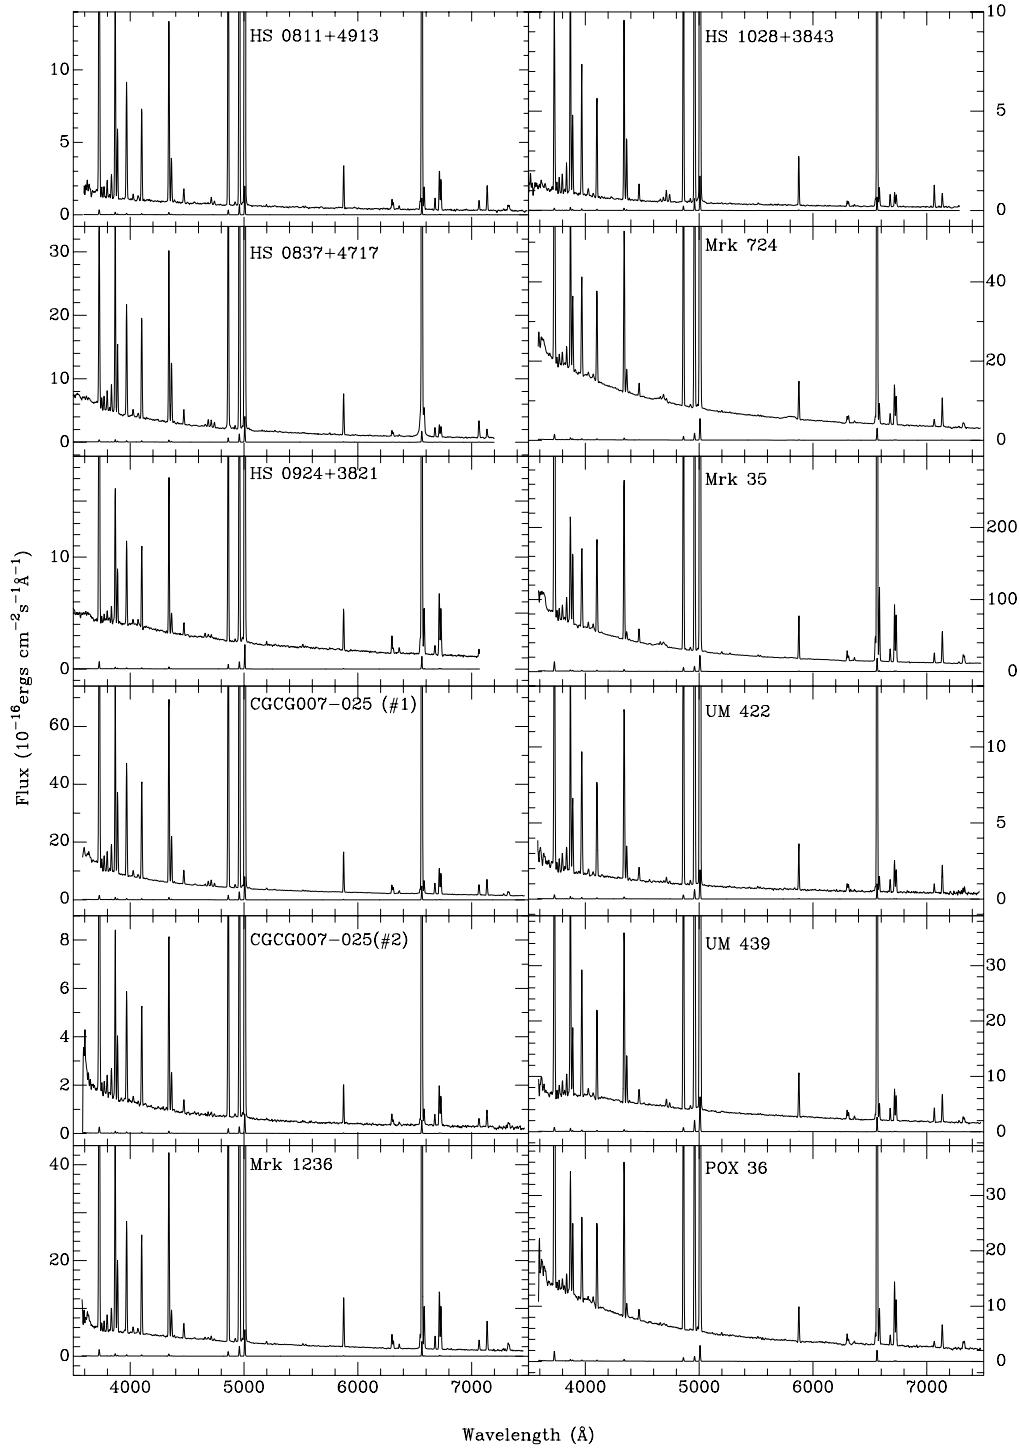

FIG. 1.—Continued

emission lines to derive  $N_e(\text{He II})$  and  $\tau(\lambda 3889)$ , i.e.,  $n = 5$ . The He I  $\lambda\lambda 3889$  and 7065 lines play an important role because they are particularly sensitive to both quantities. Since the He I  $\lambda 3889$  line is blended with the H8  $\lambda 3889$  line, we have subtracted the latter, assuming its intensity to be equal to  $0.107I(H\beta)$  (Aller 1984). However, the He<sup>+</sup> abundances derived from the He I  $\lambda 3889$  and 7065 emission lines are more uncertain as compared to those derived from other He I emission lines because of their higher sensitivity to collisional and fluorescent enhancements and, in the case of the  $\lambda 3889$  line, also because of the uncertainties due to its blending with

the H8 line. Therefore, we consider two cases, one with  $k = 5$  when all lines are used in the calculation of  $y_{\text{mean}}^+$ , and the other with  $k = 3$  when He I  $\lambda\lambda 3889$  and 7065 are excluded.

In our spectra, other He I emission lines are seen, most often He I  $\lambda\lambda 3820, 4387, 4026, 4921$ , and 7281. However, we do not attempt to use these lines for He abundance determination because they are much weaker as compared to the five brightest lines and hence have larger uncertainties (Table 3).

Concerning the atomic data, we have used in our previous work (ITL97b; IT98b; Izotov et al. 1999, 2001a; Guseva et al. 2001) the He I emissivities of Smits (1996) along with He I

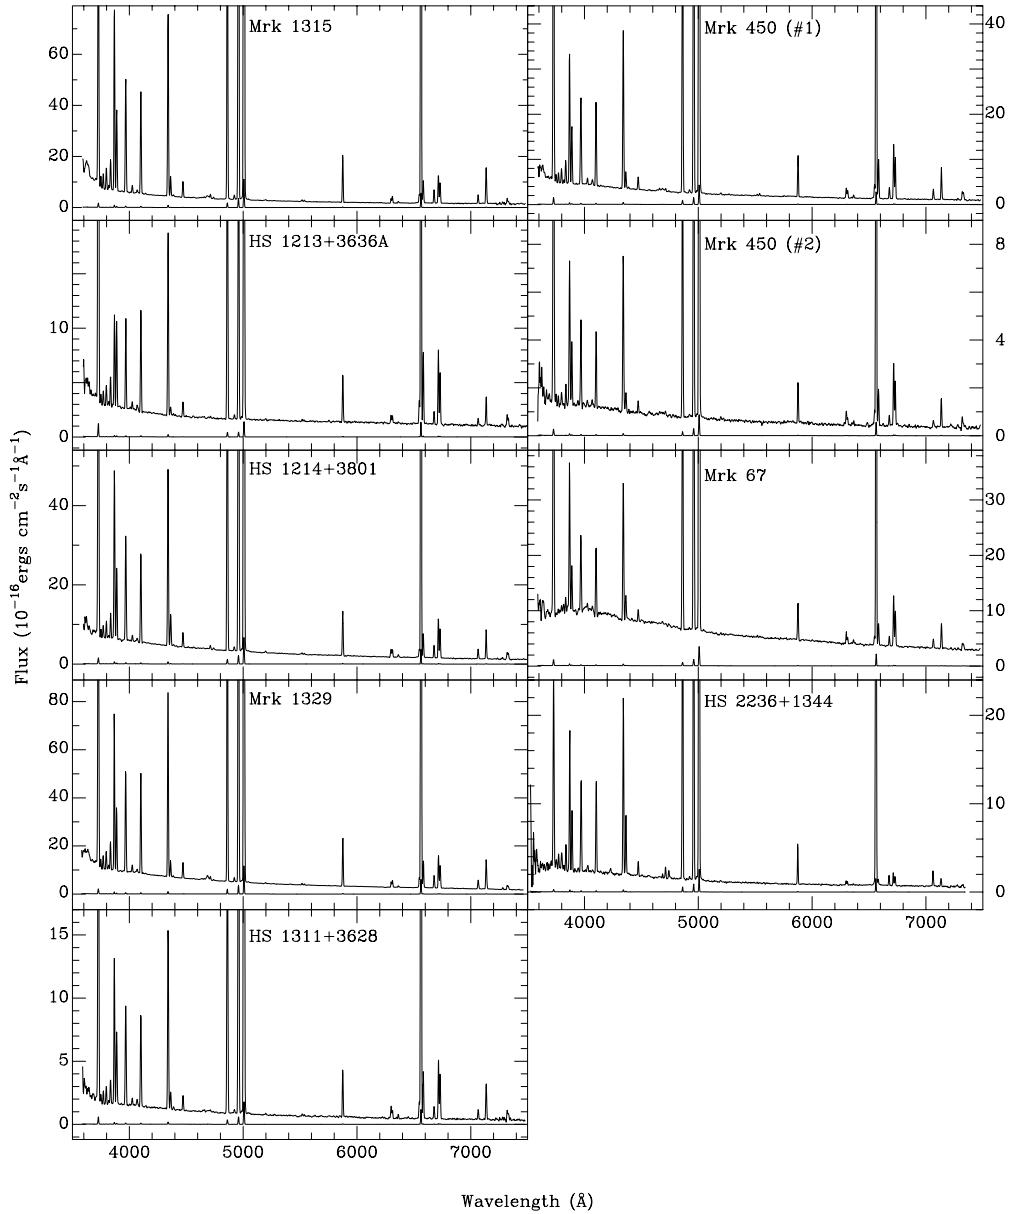

FIG. 1.—Continued

collisional enhancement coefficients of Kingdon & Ferland (1995) and fits of the fluorescent enhancement factors of Robbins (1968) by ITL97b. Recently, Benjamin, Skillman, & Smits (2002) have computed new He I emission line strengths taking into account both collisional and fluorescent enhancements. Their calculations are also based on the Smits (1996) atomic data. They give simple and convenient fits for calculations of abundances for different He I emission lines. These authors also show that some of the correction factors used by ITL97b may be in error by a factor of  $\sim 2$ , especially for the He I  $\lambda 7065$  emission line, which may lead to an overestimation of  $Y_p$ . Thus, in this paper we use the new Benjamin et al. (2002) fits to convert He I emission line strengths to singly ionized helium  $y^+ \equiv \text{He}^+/\text{H}^+$  abundances.

Additionally, in those cases when the nebular He II  $\lambda 4686$  emission line was detected, we have added the abundance of doubly ionized helium  $y^{++} \equiv \text{He}^{++}/\text{H}^+$  to  $y^+$ . The value of  $y^{++}$  is small ( $\leq 3\%$  of  $y^+$ ) in all cases.

Finally, the helium mass fraction is calculated as

$$Y = \frac{4y[1 - 20(\text{O/H})]}{1 + 4y}, \quad (3)$$

where  $y = y^+ + y^{++}$  (Pagel et al. 1992).

In Table 4 we give for each galaxy  $y^+(\lambda 4471)$ ,  $y^+(\lambda 5876)$ ,  $y^+(\lambda 6678)$ ,  $y^{++}(\lambda 4686)$ , the weighted mean helium abundance  $y$ , and the weighted mean helium mass fraction  $Y$ . The weighted mean values are derived using only the three He I  $\lambda\lambda 4471, 5876$ , and  $6678$  emission lines.

## 5. THE $dY/dZ$ SLOPE

To determine  $Y_p$  and  $dY/dZ$ , we fit the data points in the  $Y\text{-O/H}$  and  $Y\text{-N/H}$  planes by linear regression lines of the form (Peimbert & Torres-Peimbert 1974, 1976; Pagel et al. 1992)

$$Y = Y_p + \frac{dY}{d(\text{O/H})}(\text{O/H}), \quad (4)$$

$$Y = Y_p + \frac{dY}{d(\text{N}/\text{H})} (\text{N}/\text{H}). \quad (5)$$

The sample used to determine  $Y_p$  and  $dY/dZ$  is composed of 89 different observations of 82 H II regions in 76 BCGs. They are listed in Table 5 in order of increasing ionized gas metallicity. In addition to the new data for the 33 H II regions presented here (Table 1), we have also included the 45 H II regions from IT98b, the two H II regions in Tol 1214–277 and Tol 65 from Izotov et al. (2001a), the H II region in HS 1442+4250 from Guseva et al. (2003a), and H II region No. 2 in SBS 1415+437 from Guseva et al. (2003b). The number of data points (89) is larger than the number of H II regions (82) because several H II regions have independent observations from different telescopes. We treat these independent observations as separate data points in our least-squares fitting. Thus, I Zw 18 was observed with the 4 m KPNO telescope and the MMT, SBS 0335–052 with the 2.1 m KPNO telescope and with Keck (twice), SBS 0940+544 with the 4 m KPNO telescope, the MMT, and Keck, and SBS 1415+437 (No. 1) with the MMT and the 4 m KPNO telescope (twice).

In order to have a homogeneous sample with all spectra reduced and analyzed in exactly the same way, we have recalculated the He abundances of all our previously published objects with the new Benjamin et al. (2002) corrections for collisional and fluorescent enhancements.

In Figure 2 we show by solid lines the  $Y$ -O/H and  $Y$ -N/H regression lines for the whole sample. The dashed lines are  $1\sigma$  alternatives. The IT98b data are represented by open circles, other data from Izotov et al. (1999; I Zw 18 and SBS 0335–052), Thuan et al. (1999; SBS 1415+437 No. 1), Izotov et al. (2001a; Tol 1214–277 and Tol 65), Guseva et al. (2001;

SBS 0940+544), Guseva et al. (2003a; HS 1442+4250), and Guseva et al. (2003b; SBS 1415+437 No. 1 and SBS 1415+437 No. 2) by stars, and the new data presented in this paper by filled circles. Note that the sample includes now, in contrast to our previous work (ITL97b; IT98b), a significant number of the galaxies with relatively high oxygen abundances.

In Figures 2a and 2b the He abundances have been obtained using all five lines for  $\chi^2$  minimization but only three lines for abundance calculations ( $n = 5, k = 3$  in eqs. [1] and [2]). In Figures 2c and 2d all five lines are used for both  $\chi^2$  minimization and abundance calculations ( $n = k = 5$  in eqs. [1] and [2]). It can be seen that there is no systematic difference between the old and new data in Figures 2a and 2b, while the old data have systematically lower He abundances as compared to the new data in Figures 2c and 2d. This is because the He abundances derived from the He I  $\lambda 3889$  emission line, included in the second case but not in the first, are systematically lower. The He I  $\lambda 3889$  line is subject to large uncertainties introduced by the corrections for hydrogen nebular emission and stellar absorption, as discussed by Olive & Skillman (2001) using the data of IT98b. It is likely that the contribution of hydrogen absorption has been underestimated in our analysis. The effect is higher in objects with lower equivalent widths of emission lines since the relative contribution of underlying absorption is larger. This is the case for the IT98b galaxies. They generally have lower equivalent widths of the H $\beta$  emission line as compared to the galaxies in the new sample, chosen to have large EW(H $\beta$ ). Hence, the He I  $\lambda 3889$  line in the new galaxies is less affected by stellar absorption, and thus their derived  $Y$ -values are systematically higher than those of the IT98b galaxies. The He abundance

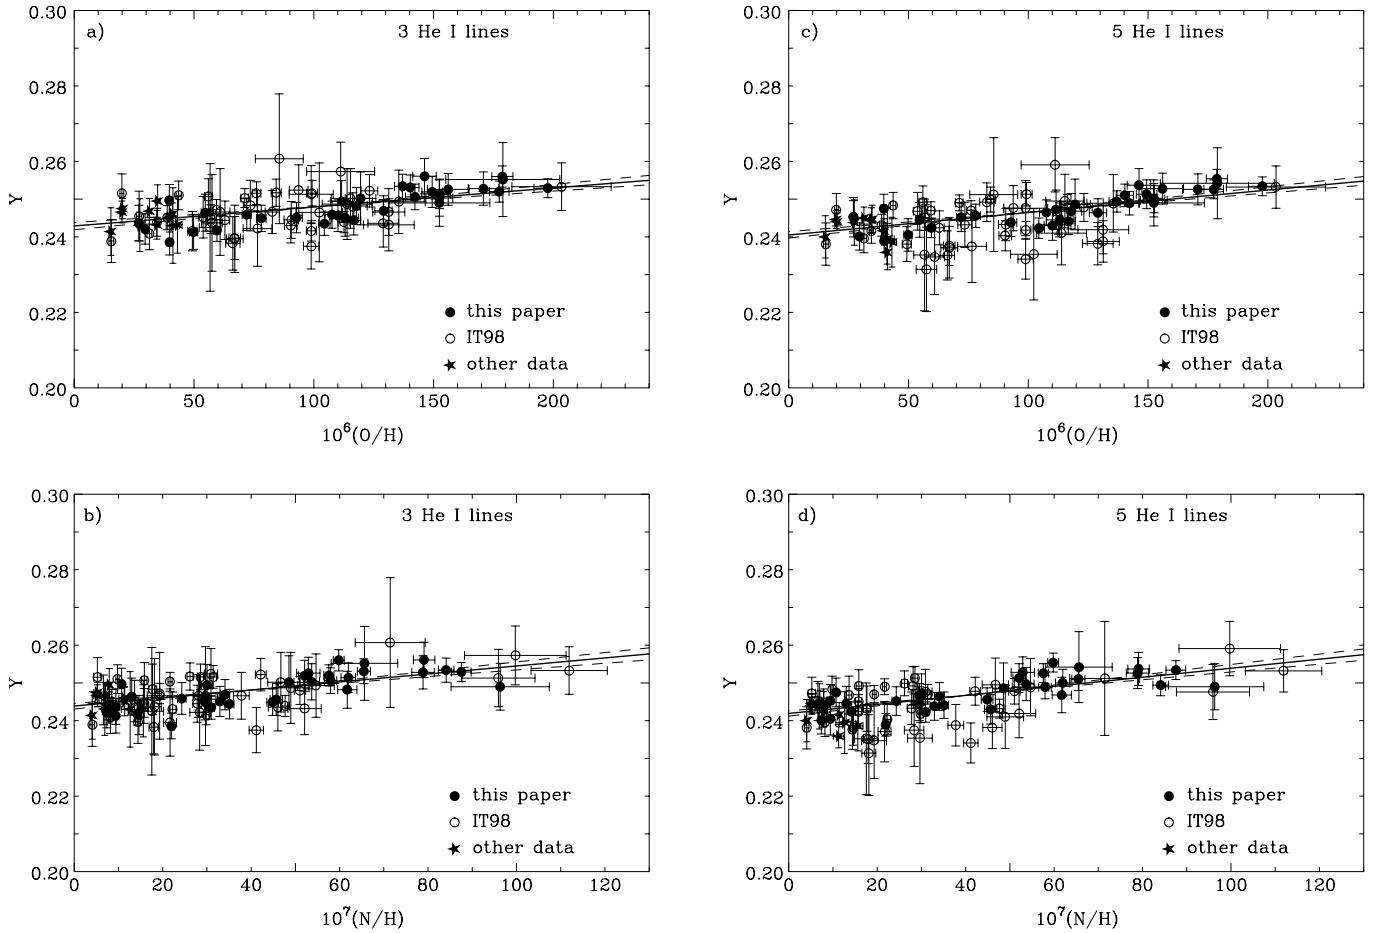

FIG. 2.—Linear regressions of the helium mass fraction  $Y$  vs. oxygen and nitrogen abundances for a total of 82 H II regions in 76 BCGs. In (a) and (b),  $Y$  was derived using the three  $\lambda\lambda 4471, 5876$ , and  $6678$  He I lines, and in (c) and (d),  $Y$  was derived using the five  $\lambda\lambda 3889, 4471, 5876, 6678$ , and  $7065$  He I lines.

derived from the He I  $\lambda 7065$  emission line is also uncertain because of its high sensitivity to collisional and fluorescent enhancements. Therefore, because they are less influenced by the aforementioned effects, the He abundances derived by using only the three He I  $\lambda\lambda 4471, 5876$ , and  $6678$  emission lines for the IT98b galaxies are much more consistent with those for the new galaxies.

The parameters of the linear regression fits for the old and (old+new) samples are given in Table 6. We also show the

dispersions  $\sigma$  of  $Y$  about the regression lines. The first row of Table 6 gives the parameters for the IT98b sample of 45 H II regions, for which we have recalculated He abundances with the Benjamin et al. (2002) equations. The primordial He abundance derived from the  $Y$ -O/H relation is  $Y_p = 0.245 \pm 0.002$ , slightly larger than the value of  $0.244 \pm 0.002$  obtained by IT98b for the same sample with the ITL97b and IT98b expressions for collisional and fluorescent enhancements of He I emission lines. The higher  $Y_p$  value is mainly the

<sup>a</sup> Data are from IT98b.

<sup>b</sup> Only collisional and fluorescent enhancements are taken into account. We have adopted  $T_e(\text{He II}) = T_e(\text{O III})$  and  $\text{ICF}(\text{He}) = 1$ .

<sup>c</sup> Collisional and fluorescent enhancements of the He I lines, collisional excitation of hydrogen lines, underlying He I stellar absorption, and differences between  $T_e(\text{He II})$  and  $T_e(\text{O III})$  are taken into account.  $\text{ICF}(\text{He})$  is set to 1.

<sup>d</sup> Calculated with  $\text{EW}_a(\text{H}8 + \text{He I } \lambda 3889) = 3.0 \text{ \AA}$ ,  $\text{EW}_a(\text{He I } \lambda 4471) = 0.4 \text{ \AA}$ ,  $\text{EW}_a(\text{He I } \lambda 5876) = 0.3 \text{ EW}_a(\text{He I } \lambda 4471)$ ,  $\text{EW}_a(\text{He I } \lambda 6678) = \text{EW}_a(\text{He I } \lambda 7065) = 0.1 \text{ EW}_a(\text{He I } \lambda 4471)$ .

<sup>e</sup> Calculated with  $\text{EW}_a(\text{H}8 + \text{He I } \lambda 3889) = 3.0 \text{ \AA}$ ,  $\text{EW}_a(\text{He I } \lambda 4471) = 0.5 \text{ \AA}$ ,  $\text{EW}_a(\text{He I } \lambda 5876) = 0.3 \text{ EW}_a(\text{He I } \lambda 4471)$ ,  $\text{EW}_a(\text{He I } \lambda 6678) = \text{EW}_a(\text{He I } \lambda 7065) = 0.1 \text{ EW}_a(\text{He I } \lambda 4471)$ .

consequence of a slope that is  $\sim 2$  times shallower [ $dY/d(\text{O/H}) = 21 \pm 21$  in Table 6 as compared to  $45 \pm 19$  in IT98b]. In the second row are given the regression parameters for the total sample. From the  $Y\text{-O/H}$  relation, we obtain  $Y_p = 0.243 \pm 0.001$ , slightly lower than the value derived from the IT98b sample because of the steeper slope [ $dY/d(\text{O/H}) = 51 \pm 9$  as compared to  $21 \pm 21$ ]. The value derived from the  $Y\text{-N/H}$  linear regression is slightly higher,  $Y_p = 0.244 \pm 0.001$ . This is because the very highest metallicity BCGs in our sample have a slightly higher N/O ratio than the lower metallicity galaxies, thus making the  $Y\text{-N/H}$  relation slightly nonlinear. This higher N/O ratio is caused by the presence of secondary nitrogen in the higher metallicity BCGs. The standard deviation of the data points is 0.004 for both  $Y\text{-O/H}$  and  $Y\text{-N/H}$  regressions, lower than for the IT98b sample. Rows 3 and 4 of Table 6 will be discussed in § 6.

The slopes of the  $Y\text{-O/H}$  and  $Y\text{-N/H}$  linear regressions can be written as

$$\frac{dY}{d(\text{O/H})} = 12 \frac{dY}{d\text{O}} = 18.2 \frac{dY}{dZ}, \quad (6)$$

$$\frac{dY}{d(\text{N/H})} = 10.5 \frac{dY}{d\text{N}} = 564 \frac{dY}{dZ}, \quad (7)$$

where O, N, and Z are, respectively, the mass fractions of oxygen, nitrogen, and heavy elements. We have assumed that  $\text{O} = 0.66Z$  (Maeder 1992) for a metallicity  $Z = 0.001$ , an initial mass function slope  $x = 1.35$  [where  $x$  is defined by  $dN/d(\log M) \propto M^x$ ], and  $\log(\text{N/H}) - \log(\text{O/H}) = -1.55$  (Thuan et al. 1995).

From Table 6 we derive  $dY/d\text{O} = 4.3 \pm 0.7$  and  $dY/dZ = 2.8 \pm 0.5$ . Although the slope  $dY/dZ$  derived here is consistent within the errors with  $dY/dZ = 2.6 \pm 1.4$  and  $3.7 \pm 1.5$  derived, respectively, by ITL97b and IT98b, we have decreased the errors on the slope by a factor of  $\sim 3$  thanks to the larger number of high-metallicity objects included in the sample. Our new value of  $dY/dZ$  is also consistent with that of  $2.1 \pm 0.4$  derived by Jimenez et al. (2003) from nearby K dwarf stars. The extrapolation of the oxygen linear regression with  $dY/d\text{O} = 4.3$  to solar metallicity gives  $Y = 0.274$ , in good agreement with  $Y = 0.271$  derived for the Sun (Christensen-Dalsgaard 1998).

The increased accuracy of our  $dY/d\text{O}$  and  $dY/dZ$  values allows us to constrain more stringently chemical evolution models. Our slope  $dY/dZ = 2.8 \pm 0.5$  appears to be too steep as compared to the values  $1.0\text{--}1.2$  obtained by Larsen, Sommer-Larsen, & Pagel (2001) with their closed-box chemical evolution models for gas-rich dwarf galaxies and their adopted  $\text{O} = 0.6Z$ . Open models with ordinary non-enriched winds, with or without gas inflow, predict also the same range of values  $1.0\text{--}1.2$ . The models of Larsen et al. (2001) with oxygen-enriched winds predict steeper slopes, more in agreement with our value, but would not fit gas mass fractions and N/O ratios simultaneously. On the other hand, analytical chemical evolution models with selective heavy-element loss (Pilyugin 1994) predict  $dY/d\text{O} > 5$  with  $dY/d\text{O}$  increasing with increasing efficiency of the oxygen-enriched galactic wind. Hence, our derived  $dY/d\text{O} = 4.3 \pm 0.7$  excludes chemical evolution models with a high mass loss of the enriched gas. Our  $dY/d\text{O}$  is in agreement with the values predicted by chemical evolution closed-box models and models with nonselective galactic winds of Carigi et al. (1999) for dwarf irregular galaxies. However, those multipa-

rameter models do not consider the evolution of some elements, such as nitrogen, and it is not clear, therefore, whether they can reproduce all the observational constraints for dwarf galaxies.

The above values were derived by neglecting other possible systematic effects, such as the difference between the electron temperatures in the He II and O III zones, underlying He I stellar absorption, the collisional excitation of hydrogen lines, and the ionization structure of the H II region. In the next section we investigate how these systematic effects may change our derived values of  $Y_p$  and  $dY/dZ$ , using a subsample of seven H II regions.

## 6. SYSTEMATIC EFFECTS

We consider successively the following four systematic effects: (1) the underlying stellar He I absorption; (2) the collisional excitation of hydrogen lines; (3) the temperature structure of the H II region, i.e., the temperature difference between  $T_e(\text{He II})$  and  $T_e(\text{O III})$ ; and (4) the ionization structure of the H II region.

### 6.1. Underlying Stellar He I Absorption

It has long been recognized (Rayo, Peimbert, & Torres-Peimbert 1982; Kunth & Sargent 1983; Dinerstein & Shields 1986; Pagel et al. 1992; Olofsson 1995) that absorption caused by hot stars in the He I lines can decrease the intensities of the nebular He I lines. In particular, Izotov & Thuan (1998a) have shown that the neglect of He I underlying stellar absorption has led to the derivation of a very low helium mass fraction in I Zw 18, the most metal-deficient BCG known (Pagel et al. 1992; Olive et al. 1997). This effect is most pronounced for the He I  $\lambda 4471$  emission line. Recently, González Delgado, Leitherer, & Heckman (1999) have produced synthetic spectra of H Balmer and He I absorption lines in starburst and post-starburst galaxies. They predict an equivalent width of the He I  $\lambda 4471$  absorption line in the range  $\sim 0.4\text{--}0.8$  Å, or  $\sim 10\%\text{--}20\%$  of the He I  $\lambda 4471$  emission line equivalent width for young starbursts with an age  $\lesssim 7$  Myr, which is the case for our H II regions. However, the equivalent width of the He I  $\lambda 3889$  absorption line is not known. González Delgado et al. (1999) predict the total equivalent width of the H8 and He I  $\lambda 3889$  absorption lines to be in the range of  $0.85\text{--}0.95$  that of the  $H\beta$  absorption line but do not give the absorption equivalent width for the He I  $\lambda 3889$  line alone. Those authors did not calculate either absorption-line equivalent widths for the other prominent He I lines, although the effect of underlying absorption appears to be smaller for the He I  $\lambda\lambda 5876, 6678$ , and  $7065$  emission lines. In any case, underlying stellar absorption must be taken into account for all He I lines if we are to achieve the desired high precision of  $\lesssim 1\%$  in the primordial He abundance determination.

### 6.2. Collisional Excitation of H Lines

It was generally assumed in abundance studies that deviations of the observed  $H\alpha/H\beta$  flux ratio from the theoretical recombination value are entirely due to interstellar extinction. Davidson & Kinman (1985) first noted that in the hot and dense H II regions of BCGs, collisional excitation of hydrogen emission lines can be important. This can affect the derived H abundances and hence the He abundances since the latter are always derived relative to H abundances. Stasińska & Izotov (2001) estimated that this effect can result in an upward correction in the He abundances of up to 5%, assuming that the

excess of the  $\text{H}\alpha/\text{H}\beta$  flux ratio above the theoretical recombination value is due only to collisional excitation. Realistically, however, the  $\text{H}\alpha/\text{H}\beta$  flux ratio excess is also partly caused by interstellar extinction, so that the effect of collisional excitation of the hydrogen lines is likely smaller,  $\sim 2\%-3\%$ , similar to the estimate of Peimbert et al. (2002).

### 6.3. Temperature Structure

To derive the He abundances, ITL94, ITL97b, and IT98b have assumed that the temperatures  $T_e(\text{He II})$  and  $T_e(\text{O III})$  averaged over the whole H II region are equal.  $T_e(\text{O III})$  is determined from the observed  $[\text{O III}]\lambda 4363/\lambda\lambda(4959+5007)$  emission line flux ratio. However, because of the high sensitivity of the flux of the auroral  $[\text{O III}]\lambda 4363$  emission line to temperature,  $T_e(\text{O III})$  tends to be characteristic of the hotter zones in the H II region, and it is generally higher than  $T_e(\text{He II})$ . To take into account the difference of the calculated electron temperature  $T_e(\text{O III})$  as compared to the one in the  $\text{H}^+$  and  $\text{He}^+$  zones, Peimbert (1967) developed a formalism based on the average temperature  $T_0$  and the mean square temperature variation  $t^2$  in an H II region. Then the temperatures  $T_e(\text{H II})$ ,  $T_e(\text{He II})$ , and  $T_e(\text{O III})$  are expressed as different functions of  $T_0$  and  $t^2$ , and  $T_e(\text{O III}) \geq T_e(\text{H II})$ ,  $T_e(\text{He II})$ . This approach has been applied by Peimbert et al. (2002) for the determination of the He abundance in some low-metallicity dwarf galaxies, including the two most metal-deficient BCGs known, I Zw 18 and SBS 0335–052. Using the observations of Izotov et al. (1999), they find that the difference between  $T_e(\text{O III})$  and  $T_e(\text{He II})$  results in a reduction of the He mass fraction by 2%–3% as compared to the case when  $T_e(\text{O III}) = T_e(\text{He II})$ .

### 6.4. Ionization Structure

Another source of systematic uncertainties comes from the assumption that the  $\text{H}^+$  and  $\text{He}^+$  zones in the H II region are coincident. However, depending on the hardness of the ionizing radiation, the radius of the  $\text{He}^+$  zone can be smaller than the radius of the  $\text{H}^+$  zone in the case of soft ionizing radiation or larger in the case of hard radiation. In the former case, a correction for unseen neutral helium should be made, resulting in an ionization correction factor  $\text{ICF}(\text{He}) > 1$  and hence a higher helium abundance. In the latter case, the situation is opposite and  $\text{ICF}(\text{He}) < 1$ . The ICF problem has been discussed in several studies (Pagel et al. 1992; Steigman, Viegas, & Gruenwald 1997; Olive et al. 1997; Viegas et al. 2000; Peimbert et al. 2000; Ballantyne, Ferland, & Martin 2000; Sauer & Jedamzik 2002). It was shown that the correction of the helium abundance can be as high as several percent in either downward or upward directions depending on the hardness of the radiation and the ionization parameter  $U$ . Sauer & Jedamzik (2002) have calculated an extensive grid of photoionized H II region models aiming to derive the correction factors as functions of hardness and  $U$ . Their conclusion was that a downward correction of  $Y$  by as much as 6% and 2% is required, respectively, for ionization parameters  $\log U = -3.0$  and  $-2.5$ . However, the downward correction is  $\lesssim 1\%$  if  $\log U \gtrsim -2.0$ , which is the case for the majority of our H II regions. Therefore, we do not consider this effect further in the present paper and set  $\text{ICF}(\text{He}) = 1$ .

### 6.5. Analysis of a Subsample of Seven H II Regions

Although these systematic effects are still poorly studied and difficult to determine precisely, Izotov et al. (2001a) have

concluded that when taken into account together, they largely offset each other. Thuan & Izotov (2002) have suggested that combining all systematic effects may push  $Y_p$  upward by at most  $\sim 2\%-4\%$ . Peimbert et al. (2002) have considered collisional and fluorescent enhancements, along with all systematic effects discussed in this section, in their analysis of the He abundance in five H II regions. They attack the problem in three steps. First, using the ionization code CLOUDY (Ferland 1996; Ferland et al. 1998), these authors estimate the parameter  $t^2$ , the optical depth  $\tau(\lambda 3889)$ , the ionization correction factor  $\text{ICF}(\text{He})$ , and the contribution of collisional enhancement to the hydrogen lines. Second, they adopt the equivalent widths of the  $\text{H I}$  and  $\text{He I}$  absorption lines calculated by González Delgado et al. (1999) for a particular age of the star formation burst in each H II region, except for NGC 346, where the equivalent widths of absorption lines were set to zero. No correction for underlying stellar absorption was applied to the strong  $\text{He I} \lambda\lambda 5876, 6678$ , and 7065 emission lines. These lines play an important role in the helium abundance determination, but their absorption equivalent widths were not calculated by González Delgado et al. (1999). Peimbert et al. (2002) then use a  $\chi^2$  minimization procedure with input parameters  $t^2$ ,  $\tau(\lambda 3889)$ ,  $T_e(\text{O III})$ , and the equivalent widths of the  $\text{He I}$  absorption lines to find new values of  $t^2$  and  $\tau(\lambda 3889)$  and derive the electron temperature  $T_e(\text{He II})$ , the electron number density  $N_e(\text{H II})$ , and the He abundance. In the case of the two most metal-deficient BCGs known, I Zw 18 and SBS 0335–052, Peimbert et al. (2002) derive, after correction for all systematic effects, helium abundances very close to the values obtained when systematic effects other than collisional and fluorescent enhancements are not taken into account. However, for three other higher metallicity H II regions in their sample, they derive also relatively low He mass fractions, similar to those of I Zw 18 and SBS 0335–052. This resulted in a very flat  $Y\text{-O/H}$  linear regression, leading these authors to conclude that they have probably overestimated the collisional excitation of hydrogen lines in I Zw 18 and SBS 0335–052, resulting in artificially high He mass fractions.

To estimate the systematic effects in our derived  $Y_p$  value in § 5 and to compare our results with those of Peimbert et al. (2002), we have analyzed the same objects as these authors: I Zw 18 and SBS 0335–052 (Izotov et al. 1999), Mrk 209 ( $\equiv$  Haro 29) and Mrk 71 (ITL97b), and NGC 346 (Peimbert et al. 2000). Because the range of oxygen abundance spanned by the five galaxies is relatively small, we have added two more metal-rich galaxies, Mrk 450 (this paper) and UM 311 (IT98b), to improve the metallicity range and obtain a more accurate determination of  $dY/dZ$ . However, our approach is somewhat different from that of Peimbert et al. (2002).

Instead of using CLOUDY to derive model parameters, we adopt the self-consistent approach that we have used in all of our previous studies and in § 4 of this paper. Our method consists of using the five strongest  $\text{He I}$  lines  $\lambda\lambda 3889, 4471, 5876, 6678$ , and 7065 and correcting for systematic effects in such a way so as to obtain after correction the best agreement between the He abundances derived from each  $\text{He I}$  line separately; i.e., we search for the minimum  $\chi^2$  as defined by equation (1). In our previous work, we have considered as free parameters the electron number density  $N_e(\text{He II})$  and the optical depth  $\tau(\lambda 3889)$ . Here we add the electron temperature  $T_e(\text{He II})$  and  $\Delta I(\text{H}\alpha)/I(\text{H}\alpha)$ , the fraction of the  $\text{H}\alpha$  flux due to collisional excitation. These values should be well

determined as we have only four unknowns for five constraints, i.e., the problem is overdetermined.

We proceed in the following manner. We first correct for collisional excitation of the hydrogen lines by varying  $\Delta I(H\alpha)/I(H\alpha)$  in the range between 0% and 5% and subtracting  $\Delta I(H\alpha)$  and  $\Delta I(H\beta)$ , respectively, from the observed fluxes of  $H\alpha$  and  $H\beta$ . We adopt  $\Delta I(H\beta)/I(H\beta) = 0.33\Delta I(H\alpha)/I(H\alpha)$  (Stasińska & Izotov 2001). Then the whole spectrum is corrected for extinction and underlying hydrogen absorption derived from the hydrogen emission line fluxes, including the new reduced  $H\alpha$  and  $H\beta$  fluxes.

Underlying  $He\ 1$  absorption constitutes a major problem as each of the  $He\ 1\ \lambda\lambda 3889, 4471, 5876, 6678$ , and  $7065$  lines has its own absorption equivalent width  $EW_a$ . Additionally,  $He\ 1\ \lambda 3889$  is blended with  $H8$  and deblending it is subject to large uncertainties because of the imperfect correction for hydrogen emission and absorption.

Because the equivalent widths of  $He\ 1$  absorption lines are dependent on the age of the star formation burst, we first need to determine the age of the burst using the equivalent width of the  $H\beta$  emission line. The values of  $EW(H\beta)$  for the  $H\>II$  regions considered in this section are in the range  $100$ – $250$  Å, which corresponds to a burst age of  $\sim 4$  Myr for the metallicity  $Z \lesssim Z_\odot/5$  (Schaerer & Vacca 1998). The equivalent widths of the  $He\ 1$  absorption lines have large variations in the age range  $3$ – $5$  Myr (González Delgado et al. 1999) and are not well constrained. In particular,  $EW_a(He\ 1\ \lambda 4471)$  at  $Z = Z_\odot/20$  varies in the range  $0.4$ – $0.6$  Å, or by a factor of  $\sim 1.5$ . As for the equivalent width of the blend  $H8 + He\ 1\ \lambda 3889$ , it varies in the range  $2.0$ – $3.9$  Å, or by a factor of  $\sim 2$ . The mean equivalent widths in the  $3$ – $5$  Myr age range are  $EW_a(He\ 1\ \lambda 4471) \approx 0.5$  Å and  $EW_a(H8 + He\ 1\ \lambda 3889) \approx 3.0$  Å. These values can be smaller if the gaseous continuum emission is significant. In the  $H\>II$  regions considered in this section, the gaseous continuum emission contributes  $\sim 10\%$ – $25\%$  of the total continuum flux at the wavelength of  $H\beta$ , reducing by the same amount the equivalent width of the  $H\beta$  absorption line. However, at shorter wavelengths the effect of gaseous continuum is smaller. We thus adopt two sets of equivalent widths: (1)  $EW_a(H8 + He\ 1\ \lambda 3889) = 3.0$  Å and  $EW_a(He\ 1\ \lambda 4471) = 0.4$  Å, which takes into account the dilution by the gaseous continuum, and (2)  $EW_a(H8 + He\ 1\ \lambda 3889) = 3.0$  Å and  $EW_a(He\ 1\ \lambda 4471) = 0.5$  Å, where gaseous continuum emission is negligible. As for the other  $He\ 1$  lines, their  $EW_a$  decrease progressively from the blue to the red (see, for example, the spectrum of I Zw 18 NW in Fig. 2 of Izotov et al. 1999, which is strongly affected by  $He\ 1$  underlying absorption and where  $He\ 1\ \lambda 4471$  is barely seen, while both  $He\ 1\ \lambda\lambda 6678$  and  $7065$  can be seen in emission). We adopt for them  $EW(He\ 1\ \lambda 5876) = 0.3EW(He\ 1\ \lambda 4471)$ ,  $EW(He\ 1\ \lambda 6678) = EW(He\ 1\ \lambda 7065) = 0.1EW(He\ 1\ \lambda 4471)$  in both cases.

For each of these two sets of  $EW_a$ , we solve the problem self-consistently to find the four parameters  $\Delta I(H\alpha)/I(H\alpha)$ ,  $T_e(He\>II)$ ,  $N_e(He\>II)$ , and  $\tau(\lambda 3889)$  using the five  $He\ 1$  emission line fluxes. We calculate  $\chi^2$ ,  $T_e(He\>II)$ ,  $N_e(He\>II)$ , and  $\tau(\lambda 3889)$  as a function of  $\Delta I(H\alpha)/I(H\alpha)$  in the range  $0\%$ – $5\%$ , in steps of  $0.0005$ , for a total of  $100$  models. The best solution corresponds to the minimum  $\chi^2$ . It is the one in which the separate helium abundances  $y$  derived from each individual  $He\ 1$  line are in best agreement with the weighted mean abundance. To exclude unphysical solutions, we consider only models with  $0.9 \leq T_e(He\>II)/T_e(O\ III) \leq 1.0$ ,  $10\ cm^{-3} \leq N_e(He\>II) \leq 450\ cm^{-3}$ , and  $0 \leq \tau(\lambda 3889) \leq 5$ . The values found by

Peimbert et al. (2002) in the analysis of their  $H\>II$  region sample fall within those ranges.

The parameters of the best models for each set of  $EW_a$  values and for each of the seven  $H\>II$  regions are shown in Table 7. The best solutions are also shown in the  $Y$ -O/H and  $Y$ -N/H planes in Figures 3a and 3b [models with  $EW_a(H8 + He\ 1\ \lambda 3889) = 3.0$  Å and  $EW_a(He\ 1\ \lambda 4471) = 0.4$  Å] and Figures 3c and 3d [models with  $EW_a(H8 + He\ 1\ \lambda 3889) = 3.0$  Å and  $EW_a(He\ 1\ \lambda 4471) = 0.5$  Å]. The corresponding linear regression parameters are given in Table 6.

Our derived values of  $Y$  are in general higher than the ones obtained by Peimbert et al. (2002) for the same  $H\>II$  regions. The differences come from the different ways our and their  $Y$ -values have been derived: instead of estimating the physical parameters of the  $H\>II$  regions by CLOUDY, we have adopted an approach that does not depend on any particular physical model, external estimates, or assumptions; i.e., we simply search the multiparameter space for the smallest  $\chi^2$ . Other differences are as follows: (1) we have included  $H\>II$  regions with higher metallicities to derive a more accurate  $dY/dZ$  slope; (2) Peimbert et al. (2002) used expressions for collisional enhancement of  $He\ 1$  emission lines from Benjamin, Skillman, & Smits (1999), while we use the expressions by the same authors (Benjamin et al. 2002) but that include not only collisional but also fluorescent enhancement; (3) Peimbert et al. (2002) assumed no underlying  $He\ 1$  absorption for NGC 346, while we find it to be significant; and (4) Peimbert et al. (2002) calculate their  $\chi^2$  in a slightly different manner from us. They use the expression from Peimbert et al. (2000) weighting by errors of line fluxes, while we use equation (1) weighting by errors of He abundances. However, we have checked (for NGC 346) that the choice of a weighting scheme makes little difference in the derived He abundance. The largest differences between Peimbert et al. (2002) and our values of  $Y$  are for NGC 346 and Mrk 209, our values being  $\sim 2\%$ – $3\%$  higher.

For the set  $EW(\lambda 3889) = 3.0$  Å and  $EW(\lambda 4471) = 0.4$  Å we derive a primordial He mass fraction  $Y_p = 0.2421 \pm 0.0021$  from the  $Y$ -O/H linear regression and  $0.2446 \pm 0.0016$  from the  $Y$ -N/H linear regression. For the set  $EW(\lambda 3889) = 3.0$  Å and  $EW(\lambda 4471) = 0.5$  Å,  $Y_p = 0.2444 \pm 0.0020$  from the  $Y$ -O/H linear regression and  $0.2466 \pm 0.0016$  from the  $Y$ -N/H linear regression. The  $Y_p$  values obtained from the  $Y$ -O/H linear regressions considering known systematic effects are very similar to the value  $Y_p = 0.243 \pm 0.001$  derived in § 5 for the whole sample without correcting for the difference between  $T_e(He\>II)$  and  $T_e(O\ III)$ , the collisional excitation of hydrogen lines, and the underlying stellar absorption in the  $He\ 1$  lines. Thus, the combined effect of the corrections for all known systematic effects turned out to be very small. In the more realistic case where gaseous continuum is taken into account, the  $Y_p$  values differ by only 0.4%. In the case where it is not taken into account, they differ by 0.6%.

This means that, even if all known systematic effects are taken into account in our previous work on the statistical derivation of  $Y_p$  by linear regressions (ITL94; ITL97b; IT98b), the result will not be changed. While each individual systematic effect can change  $Y$  upward or downward by as much as 4%, they work in the opposite sense and nearly cancel each other out. By nearly doubling our sample (from 45 to 82  $H\>II$  regions) and choosing the galaxies so that they span as large a metallicity range as possible, we have considerably reduced the uncertainties in the slopes  $dY/dO = 4.3 \pm 0.7$  and  $dY/dZ = 2.8 \pm 0.5$  for the whole sample, as compared to  $dY/dO = 5.7 \pm 1.8$  and  $dY/dZ = 3.7 \pm 1.2$  for the restricted

<sup>a</sup> Ratio of the absorption-line-to-emission-line equivalent widths.

<sup>b</sup> Calculated with  $T_e(\text{He II})$ .

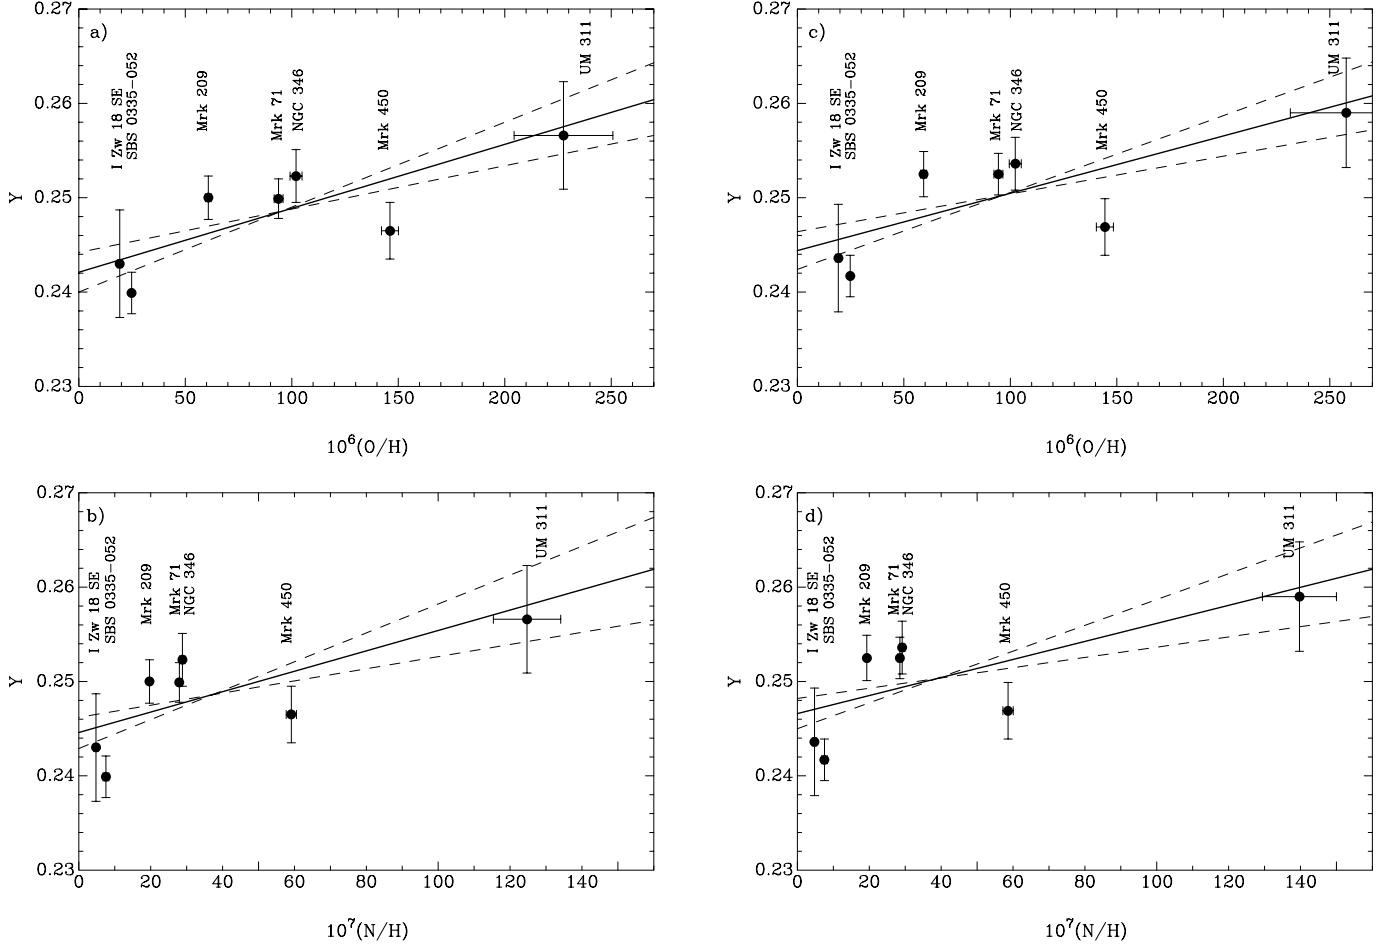

FIG. 3.—(a, c) Y-O/H and (b, d) Y-N/H linear regressions (solid lines) for seven H II regions. Their helium mass fraction  $Y$  has been corrected for known systematic effects by a  $\chi^2$  minimization procedure (see § 6). The filled circles represent the solution with the lowest  $\chi^2$ . Oxygen and nitrogen abundances for all points are calculated by setting the electron temperatures in the O III zone equal to  $T_e(\text{He II})$ , the latter being derived from  $\chi^2$  minimization. The equivalent widths of the absorption lines adopted in (a) and (b) are  $\text{EW}_a(\lambda 3889) = 3.0 \text{ \AA}$ ,  $\text{EW}_a(\lambda 4471) = 0.4 \text{ \AA}$ ,  $\text{EW}_a(\lambda 5876) = 0.17 \text{ \AA}$ , and  $\text{EW}_a(\lambda 6678) = \text{EW}_a(\lambda 7065) = 0.05 \text{ \AA}$ . The corresponding values in (c) and (d) are  $\text{EW}_a(\lambda 3889) = 3.0 \text{ \AA}$ ,  $\text{EW}_a(\lambda 4471) = 0.5 \text{ \AA}$ ,  $\text{EW}_a(\lambda 5876) = 0.17 \text{ \AA}$ , and  $\text{EW}_a(\lambda 6678) = \text{EW}_a(\lambda 7065) = 0.05 \text{ \AA}$ .

sample with  $\text{EW}_a(\lambda 4471) = 0.4 \text{ \AA}$  and  $dY/dO = 5.1 \pm 1.8$  and  $dY/dZ = 3.4 \pm 1.2$  with  $\text{EW}_a(\lambda 4471) = 0.5 \text{ \AA}$ . These values are consistent within the errors with our previous determinations. In a future paper we will apply the  $\chi^2$  minimization technique to correct our whole sample of 82 H II regions for known systematic effects and reduce further the uncertainties in  $Y_p$  and  $dY/dZ$ . We will study in detail another possible additional systematic effect, that of the ionization structure of H II regions, which we have not considered in this paper, simply setting the ICFs of He I to 1.

## 7. COSMOLOGICAL IMPLICATIONS

With our value of  $Y_p = 0.2421 \pm 0.0021$  for  $\text{EW}_a(\lambda 4471) = 0.4 \text{ \AA}$  and with an equivalent number of light neutrino species equal to 3, the SBBN model gives  $\eta_{10} = 10^{10}\eta = 3.4^{+0.7}_{-0.6}$ , where  $\eta$  is the baryon-to-photon number ratio and the error bars denote  $1\sigma$  errors. This corresponds to a baryonic mass fraction  $\Omega_b h^2 = 0.012^{+0.003}_{-0.002}$ . The respective values of the cosmological parameters with  $Y_p = 0.2444 \pm 0.0020$  [obtained for  $\text{EW}_a(\lambda 4471) = 0.5 \text{ \AA}$ ] are  $\eta_{10} = 10^{10}\eta = 4.0^{+1.1}_{-0.5}$  and  $\Omega_b h^2 = 0.015^{+0.003}_{-0.002}$ . These values are lower at the  $2\sigma$  level than  $\Omega_b h^2 = 0.021 \pm 0.002$  from recent measurements of the deuterium abundance in damped Ly $\alpha$  systems (Kirkman et al. 2003). The latter would correspond to  $Y_p = 0.2476^{+0.0009}_{-0.0010}$ . Recent measurements of the fluctuations of the microwave

background radiation by *Wilkinson Microwave Anisotropy Probe (WMAP)* observations have improved considerably the precision of  $\eta$  (Spergel et al. 2003). The *WMAP* data give  $\Omega_b h^2 = 0.0224 \pm 0.0009$ , corresponding to  $Y_p = 0.2483 \pm 0.0004$  in the SBBN model, significantly higher than our values of  $Y_p$ , and inconsistent at the 95% CL.

If, with improved determinations,  $\eta$  as obtained from the deuterium abundance and microwave background fluctuation measurements remains systematically higher than its value obtained from the He abundance, then this may suggest deviations from SBBN theory. One possibility is that the equivalent number of the light neutrino species  $N_\nu$  is less than 3. Combining  $\Omega_b h^2 = 0.0224 \pm 0.0009$  obtained by *WMAP* (Spergel et al. 2003) with  $Y_p = 0.2421 \pm 0.0021$ , we obtain  $N_\nu = 2.48$  with an upper limit  $N_\nu < 2.83$  at the 95% CL (Walker et al. 1991). With  $Y_p = 0.2444 \pm 0.0020$ , we obtain  $N_\nu = 2.67$  with an upper limit  $N_\nu < 3.01$  at the 95% CL.

## 8. SUMMARY AND CONCLUSIONS

We present in this paper new high signal-to-noise ratio spectrophotometric observations of 31 low-metallicity blue compact galaxies (BCGs), containing 33 H II regions and spanning a large range of heavy-element mass fractions from  $\sim Z_\odot/30$  to  $Z_\odot/4$ . We combine these new data with our

previous data (Izotov & Thuan 1998b) to construct a sample of 82 H II regions and determine the primordial helium mass fraction  $Y_p$  by linear regressions to the sample. Our sample constitutes one of the largest and most homogeneous (obtained, reduced, and analyzed in the same way) data sets now available for the determination of  $Y_p$ .

We have considered known systematic effects on the He abundance determination. For the total sample of 82 H II regions we have calculated  $N_e(\text{He II})$  self-consistently and taken into account the effects of collisional and fluorescent enhancements. For a restricted sample of six H II regions from our sample and an additional H II region, NGC 346 in the Small Magellanic Cloud, we have examined, in addition to the collisional and fluorescent enhancements of He I emission lines, the effects of collisional excitation of hydrogen emission lines, of underlying stellar He I absorption, and of the difference between the temperature  $T_e(\text{He II})$  in the  $\text{He}^+$  zone and the temperature  $T_e(\text{O III})$  derived from the [O III]  $\lambda\lambda 4363/\lambda\lambda (4959+5007)$  flux ratio. The restricted sample was chosen because the systematic effects on the  $Y_p$  determination of five of the galaxies in the sample have been discussed by Peimbert et al. (2002), and we can compare our results to theirs.

We have derived the following results:

1. Although each systematic effect may move the helium mass fraction  $Y$  up or down by as much as 4%, the combined result of the systematic effects on the restricted sample is relatively small ( $\lesssim 0.6\%$ ), as they act in the opposite sense and mostly cancel each other out. We derive for the restricted sample  $Y_p = 0.2421 \pm 0.0021$  adopting  $\text{EW}_a(\lambda 4471) = 0.4 \text{ \AA}$ . This corresponds to a baryonic mass fraction  $\Omega_b h^2 = 0.012^{+0.003}_{-0.002}$ . If  $\text{EW}_a(\lambda 4471) = 0.5 \text{ \AA}$  is adopted, then  $Y_p =$

$0.2444 \pm 0.0020$ , corresponding to  $\Omega_b h^2 = 0.015^{+0.003}_{-0.002}$ . These values of  $\Omega_b h^2$  are lower than the values derived from the deuterium abundance and microwave background radiation fluctuation measurements. This may indicate that the equivalent number of light neutrino species  $N_\nu$  is less than 3 and hence that there are deviations from the standard big bang nucleosynthesis model.

2. The slopes  $dY/dO$  and  $dY/dZ$  derived from the Y-O/H linear regressions for the restricted sample with two adopted values of  $\text{EW}_a(\lambda 4471) = 0.4$  and  $0.5 \text{ \AA}$  are, respectively,  $5.7 \pm 1.8$ ,  $3.7 \pm 1.2$  and  $5.1 \pm 1.8$ ,  $3.4 \pm 1.2$ . They are consistent with previous determinations by ITL97b and Izotov & Thuan (1998b) using BCGs and by Jimenez et al. (2003) from nearby K dwarf stars.

3. We have considerably reduced the errors in the  $dY/dO$  and  $dY/dZ$  slopes derived for the whole sample as it contains galaxies spanning a wide range of metallicities, which was not the case in our previous work. From the Y-O/H linear regression of the whole sample, with only collisional and fluorescent enhancements taken into account, we derive slopes  $dY/dO = 4.3 \pm 0.7$  and  $dY/dZ = 2.8 \pm 0.5$ , in good agreement with the slopes derived from the subsample of seven H II regions where all known systematic effects, with the exception of ionization correction effects, are taken into account.

Y. I. I. is grateful to the staff of the Astronomy Department at the University of Virginia for warm hospitality. Y. I. I. and T. X. T. acknowledge the support of National Science Foundation grant AST 02-05785.
