## ABSTRACT

We present a comparison between the observed color distribution, number, and mass density of massive galaxies at $1.5 < z < 3$ and a model by Hopkins et al. that relates the quasar and galaxy population on the basis of gas-rich mergers. In order to test the hypothesis that quiescent red galaxies are formed after a gas-rich merger involving quasar activity, we confront photometry of massive ($M > 4 \times 10^{10}\ M_\odot$) galaxies extracted from the FIRES, GOODS-South, and MUSYC surveys, together spanning an area of 496 arcmin$^2$, with synthetic photometry from hydrodynamical merger simulations. As in the Hopkins et al. model, we use the observed quasar luminosity function to estimate the merger rate. We find that the synthetic $U - V$ and $V - J$ colors of galaxies that had a quasar phase in their past match the colors of observed galaxies that are best characterized by a quiescent stellar population. At $z \sim 2.6$, the observed number and mass density of quiescent red galaxies with $M > 4 \times 10^{10}\ M_\odot$ is consistent with the model in which every quiescent massive galaxy underwent a quasar phase in the past. At $z \sim 1.9$, 2.8 times less quiescent galaxies are observed than predicted by the model as descendants of higher redshift quasars. The merger model also predicts a large number and mass density of galaxies undergoing star formation driven by the merger. We find that the predicted number and mass density accounts for 30%–50% of the observed massive star-forming galaxies. However, their colors do not match those of observed star-forming galaxies. In particular, the colors of dusty red galaxies (accounting for 30%–40% of the massive galaxy population) are not reproduced by the simulations. Several possible origins of this discrepancy are discussed. The observational constraints on the validity of the model are currently limited by cosmic variance and uncertainties in stellar population synthesis and radiative transfer.

*Key words:* galaxies: evolution – galaxies: formation – galaxies: high-redshift – galaxies: stellar content

## 1. INTRODUCTION

In recent years, deep near-infrared (NIR) and mid-infrared (MIR) observations have revealed significant populations of red galaxies at redshifts $z \sim 2$ and above (Franx et al. 2003; Daddi et al. 2004; Yan et al. 2004). The population of distant red galaxies (DRGs), selected by the simple observed color criterion $J - K > 2.3$, makes up 66% in number and 73% in mass of the $2 < z < 3$ galaxy population at the high-mass end ($M > 10^{11}\ M_\odot$; van Dokkum et al. 2006, see also Marchesini et al. 2007). Probing to lower masses, Wuyts et al. (2007) found that the lower mass galaxies at redshifts $2 < z < 3.5$ have bluer rest-frame $U - V$ colors compared to the most massive galaxies. A substantial fraction of the massive red galaxies at high redshift are best characterized by a quiescent stellar population on the basis of their broad-band spectral energy distributions (SEDs; Labbé et al. 2005; Wuyts et al. 2007) and the presence of a

Balmer/4000 Å break and absence of emission lines in their rest-frame optical spectra (Kriek et al. 2006).

Any satisfying theory of galaxy formation has to account for the presence and abundance of these massive red galaxies in the early universe, a condition that was by no means met by the state-of-the-art hierarchical galaxy formation models at the time of their discovery (Somerville 2004).

In the meantime, merger scenarios involving active galactic nucleus (AGN) activity have been invoked by semianalytic models (Granato et al. 2004; Croton et al. 2006; Bower et al. 2006; De Lucia & Blaizot 2007; Somerville et al. 2008) and hydrodynamical simulations (Springel et al. 2005a; Di Matteo et al. 2005) to explain simultaneously the mass build-up of galaxies and the shutdown of star formation. Such an evolutionary scenario predicts an obscured (and thus red) starburst phase and ends with a quiescent (and thus red) remnant galaxy (e.g., Hopkins et al. 2006a). Observational support for the connection between dust-enshrouded starbursts, merging, and AGN activity from samples of nearby Ultra-Luminous Infrared Galaxies (ULIRGs) dates from as early as Sanders et al. (1988). Furthermore, the observed relation between the

---

supermassive black hole (SMBH) mass and the mass (Magorrian et al. [1998]) or the velocity dispersion (Ferrarese & Merritt [2000]; Gebhardt et al. [2000]) of their host suggests that black hole and galaxy growth are intimately connected. This scaling relation can be reproduced by merger simulations with implemented AGN feedback (Di Matteo et al. [2005]; Robertson et al. [2006b]).

Motivated by the observed and simulated correlations between the properties of SMBHs and their hosts, Hopkins et al. ([2006b]) used the observed quasar luminosity function to derive the galaxy merger rate as a function of mass. This paper uses the merger rate function derived by this model in combination with hydrodynamical smoothed particle hydrodynamics (SPH) simulations by Robertson et al. ([2006a]) and T. J. Cox to predict the color distribution, number, and mass density of massive galaxies in the redshift range $1.5 < z < 3$ under the assumption that each galaxy once had or will undergo a quasar phase. We compare the results to mass-limited samples in the same redshift interval, extracted from the multiwavelength surveys FIRES (Franx et al. [2000]; Labbé et al. [2003]; Förster Schreiber et al. [2006a]), GOODS-South (Giavalisco et al. [2004]; Wuyts et al. [2008]), and MUSYC (Quadri et al. [2007]).

The model we analyze in this paper resides in a much larger context that predicts that morphological transformations, starbursts, quasars, and the growth of structure are driven by galaxy mergers. This model has been well calibrated to many observations at low redshift (e.g., Jonsson et al. [2006] and Rocha et al. [2008] on attenuation of local spiral galaxies and mergers; Hopkins et al. [2008], [2009] on the structure of local ellipticals) and high redshift (e.g., Younger et al. [2009] and Narayanan et al. [2009] on the IR output of high-redshift (Ultra-)Luminous InfraRed Galaxies and Sub-Millimeter Galaxies). Here, we study the epoch of $1.5 < z < 3$, when AGN and star formation activity were at its peak, and consider specifically whether the observations of massive galaxies can be understood within this context. The comparison aims to shed light on the nature of massive galaxies and their evolutionary history, as well as identify where refinements to the model are needed.

We give an overview of the observations and simulations in Sections 2 and 3, respectively. Next, the sample selection is explained in Section 4. Section 5 addresses the methodology to populate a model universe with the binary merger simulations in order to predict number densities, mass densities, and color distributions. We compare the predicted abundance of massive galaxies by the model to the observations in Section 6. The optical and optical-to-NIR color distribution of observed and simulated massive galaxies will be addressed in Section 7, followed by a discussion of their specific star formation rates (SFRs; Section 8) and of the number and mass density of quiescent and star-forming massive galaxies in Section 9. We briefly compare observed and modeled pair statistics (Section 10) and address a few caveats on the observational and modeling results in Section 11. Finally, we summarize results in Section 12.

We work in the AB magnitude system throughout this paper and adopt a $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_M = 0.3$, $\Omega_\Lambda = 0.7$ cosmology.

## 2. OVERVIEW OF THE OBSERVATIONS

### 2.1. Fields, Coverage, and Depth

We combine $K_s$-band selected catalogs of three different surveys: FIRES, GOODS-South, and MUSYC. The reduction and photometry of the FIRES observations of the Hubble Deep Field South (HDFS) is presented by Labbé et al. ([2003]) and was later augmented with Infrared Array Camera (IRAC) data. The field reaches a $K_s$-band depth of 25.6 mag (AB, $5\sigma$ for point sources) and covers 5 arcmin$^2$. It was exposed in the WFPC2 $U_{300}$, $B_{450}$, $V_{606}$, $I_{814}$ passbands, the ISAAC $J_s$, $H$, and $K_s$ bands, and the four IRAC channels. Following similar procedures, a $K_s$-band selected catalog for the FIRES MS 1054–03 field was constructed by Förster Schreiber et al. ([2006a]). The field, covering 19 arcmin$^2$, has a $K_s$-band depth of 25 mag (AB, $5\sigma$ for point sources). The catalog comprises FORS1 $U$, $B$, and $V$, WFPC2 $V_{606}$, and $I_{814}$, ISAAC $J$, $H$, and $K_s$, and IRAC 3.6–8.0 $\mu$m photometry.

Over a significantly larger area (114 arcmin$^2$), but to a shallower depth, a $K_s$-band selected catalog, dubbed FIREWORKS, was constructed based on the publicly available GOODS-South data (Wuyts et al. [2008]). The variations in exposure time and observing conditions between the different ISAAC pointings lead to an inhomogeneous depth over the whole GOODS-South field. The 90% completeness level in the $K_s$-band mosaic is reached at an AB magnitude of $K_{\rm tot, AB} = 23.7$. The photometry was performed in an identical way to that of the FIRES fields, allowing a straightforward combination of the three fields. The included passbands are the ACS $B_{435}$, $V_{606}$, $i_{775}$, and $z_{850}$ bands, the ISAAC $J$, $H$, and $K_s$ bands, and the four IRAC channels. We also use the ultradeep MIPS 24 $\mu$m (20 $\mu$Jy, $5\sigma$) imaging of the GOODS-South field. As for the IRAC bands, we used the information on position and extent of the sources from the higher resolution $K_s$-band image to reduce confusion effects on the 24 $\mu$m photometry (I. Labbé et al. 2009, in preparation).

Finally, we complement the FIRES and GOODS-South imaging with optical-to-MIR observations of the MUSYC HDFS1, HDFS2, 1030, and 1255 fields for parts of our analysis. The $K_s$-band selected catalogs, augmented with IRAC photometry, are presented by Marchesini et al. ([2008]). Together, the MUSYC fields span an area of 358 arcmin$^2$. They reach the 90% completeness level at $K_{\rm tot, AB} = 22.7$. Given their shallower depth, they will only be used in the analysis of the most massive ($M > 10^{11} M_\odot$) high-redshift galaxies.

### 2.2. Redshifts and Rest-frame Photometry

Despite the large number of spectroscopic campaigns in the GOODS-South and FIRES fields, the fraction of $K_s$-selected $1.5 < z < 3$ galaxies that is spectroscopically confirmed is only 9%. The fraction drops to 3% when the MUSYC fields are included. Therefore, a reliable estimate of the photometric redshift is crucial in defining robust samples of massive high-redshift galaxies.

Wuyts et al. ([2008]) used the EAZY photometric redshift code by Brammer et al. ([2008]) to fit a non-negative linear combination of galaxy templates to the FIREWORKS $U_{38}$-to-8 $\mu$m SEDs of galaxies in the GOODS-South field. We applied an identical procedure to galaxies in the FIRES fields. The template set was constructed from a large number of PÉGASE models (Fioc & Rocca-Volmerange [1997]). It consists of five principal component templates that span the colors of galaxies in the semianalytic model by De Lucia & Blaizot ([2007]), plus an additional template representing a young (50 Myr) and heavily obscured ($A_V = 2.75$) stellar population to account for the existence of dustier galaxies than present in the semianalytic model. A template error function was applied to downweight the rest-frame UV and rest-frame NIR during the fitting procedure. The $K_s$-band magnitude $m_0$ was used as a prior in constructing the redshift probability distribution $p(z|C, m_0)$ for a galaxy with

colors $C$. We adopt the value $z_{mp}$ of the redshift marginalized over the total probability distribution,

$$z_{mp} = \frac{\int z\, p(z|C, m_0)\, dz}{\int p(z|C, m_0)\, dz}, \qquad (1)$$

as best estimate of the galaxy's redshift.

The uncertainties in the photometric redshifts were determined from Monte Carlo simulations. For each galaxy, a set of 100 mock SEDs was created by perturbing each flux point according to its formal error bar, and repeating the $z_{phot}$ computation. The lower and upper error on $z_{phot}$ comprise the central 68% of the Monte Carlo distribution.

We tested the quality of the photometric redshifts in two ways. First, we compare them to the available spectroscopic redshifts in the $1.5 < z < 3$ interval, resulting in a normalized median absolute deviation $\sigma_{NMAD}\left(\frac{z_{phot}-z_{spec}}{1+z_{spec}}\right) = 0.075$. The quality measure $\sigma_{NMAD}$ remains the same when the spectroscopic redshifts in the MUSYC fields are included or excluded. Second, we tested how well we could recover the redshift from synthetic broad-band photometry of simulated SPH galaxies placed at redshifts 1.5 to 3. We found that the considered template set performed very well ($\sigma_{NMAD}(\Delta z/(1 + z)) = 0.027$). The scatter in the comparison to spectroscopically confirmed galaxies is larger than that derived from the simulations. This is likely due to the fact that the synthetic photometry is based on the same stellar population synthesis code as the template set used to recover the redshifts. Therefore, the second test only studies the impact of an unknown star formation history, dust, and metallicity distribution on the derived $z_{phot}$.

We computed the rest-frame photometry by interpolating between observed bands using the best-fit templates as a guide. Uncertainties in the rest-frame colors were derived from the same Monte Carlo simulations mentioned above, and comprise both a contribution from photometric uncertainties and from $z_{phot}$ uncertainties. For a detailed description, we refer the reader to Rudnick et al. (2003). We used an IDL implementation of the algorithm by Taylor et al. (2009) dubbed "InterRest."

### 2.3. Stellar Masses

The stellar masses of the observed galaxies in FIRES and GOODS-South were derived by N. M. Förster Schreiber et al. (2009, in preparation) following the procedure described by Wuyts et al. (2007). The stellar masses of galaxies in MUSYC were derived with the same method by Marchesini et al. (2008). Briefly, we fit BC03 templates to the optical-to-8 $\mu$m SED with the HYPERZ stellar population fitting code, version 1.1 (Bolzonella et al. 2000). We allow the following star formation histories: a single stellar population (SSP) without dust, a constant star formation history (CSF) with dust, and an exponentially declining star formation history with an $e$-folding timescale of 300 Myr ($\tau_{300}$) with dust. The allowed $A_V$ values ranged from 0 to 4 in step of 0.2, and the attenuation law applied was taken from Calzetti et al. (2000). We constrain the time since the onset of star formation to lie between 50 Myr and the age of the universe at the respective redshift. Finally, we scale from a Salpeter (1955) initial mass function (IMF) with lower and upper mass cutoffs of 0.1 $M_\odot$ and 100 $M_\odot$ to a pseudo-Kroupa IMF by dividing the stellar masses by a factor of 1.6 (Franx et al. 2008). Whereas we adopt the BC03 models for our default analysis, we also performed the SED modeling with templates from Maraston (2005, hereafter M05) and otherwise

identical settings. We indicate the results based on M05 models in the plots, and comment on them where relevant. On average, estimated stellar masses are lower by a factor of 1.5 when M05 models are used.

### 2.4. Star Formation Rates

We derived estimates of the total (unobscured plus obscured) SFR of the observed galaxies by adding the UV and IR light, scaled by the calibrations for the local universe (Kennicutt 1998):

$$\text{SFR}[M_\odot\, \text{yr}^{-1}] = 1.74 \times 10^{-10}(L_{IR} + 3.3L_{2800})/L_\odot, \qquad (2)$$

where the rest-frame luminosity $L_{2800} \equiv \nu L_\nu(2800\,\text{Å})$ was derived from the observed photometry with the algorithm by Rudnick et al. (2003). The total IR luminosity $L_{IR} \equiv L(8-1000\,\mu\text{m})$ was derived from the observed 24 $\mu$m flux density in combination with the photometric redshift estimate (spectroscopic when available) following the prescription of Dale & Helou (2002). As best estimate, we adopt the mean of the logarithm of all conversion factors corresponding to the Dale & Helou (2002) IR SEDs within the range $\alpha = 1-2.5$, where $\alpha$ parameterizes the heating intensity level from active ($\alpha = 1$) to quiescent ($\alpha = 2.5$) galaxies.[14] The variation from $L_{IR,\alpha=2.5}$ to $L_{IR,\alpha=1}$ is 0.9 dex in the redshift interval $1.5 < z < 3$. Where relevant, we indicate this systematic uncertainty in the conversion from 24 $\mu$m to $L_{IR}$ and eventually SFR in the plots.

### 3. OVERVIEW OF THE SIMULATIONS

We use a set of SPH (Lucy 1977; Gingold & Monaghan 1977) simulations performed by Robertson et al. (2006a) and T. J. Cox of coplanar and tilted, equal-mass, gas-rich ($f_{gas} = 0.8$ at the start of the simulation) mergers over a range of galaxy masses. In Section 11, the validity of an equal-mass merger assumption is further discussed in the light of alternative mechanisms such as minor mergers (Section 11.5) and smooth accretion flows (Section 11.6). A description of the GADGET-2 code used to run the simulations is given by Springel et al. (2005b). Springel & Hernquist (2003) describe the prescriptions for star formation and supernova feedback. The interplay between the SMBH(s) and the environment is discussed by Springel et al. (2005b). We refer the reader to Robertson et al. (2006a) for specifications on this particular set of simulations and an explanation of how the progenitors were scaled to approximate the structure of disk galaxies at redshift $z = 3$. The mass resolution varied from $\log m_i \simeq 5$ per stellar particle for the lowest mass runs to $\log m_i \simeq 6.5$ per stellar particle for the most massive mergers. The photometry of the snapshots, stored with a time resolution of 14 Myr for the tilted and 70 Myr for the coplanar runs, was derived in postprocessing as described by Wuyts et al. (2009).

Briefly, the total attenuated SED for a given snapshot consisting of $N$ stellar particles is computed as follows:

$$L_{Att,tot}(\lambda) = \sum_{i=1}^{N} m_i \cdot L_{Int}(\text{age}_i, Z_i, \lambda)$$
$$\cdot \exp\left[-N_{H_{i,los}} \cdot \frac{Z_{i,los}}{Z_\odot} \cdot \sigma(\lambda)\right], \qquad (3)$$

---

[14] We release the 24 $\mu$m-to-SFR conversion in table format at http://www.strw.leidenuniv.nl/fireworks.

where $m_i$, age$_i$, and $Z_i$ are, respectively, the mass, age, and metallicity of stellar particle $i$ that is treated as an SSP. $L_{Int}$ is the intrinsic (unattenuated) SED interpolated from a grid of templates from a stellar population synthesis code. Here, we use SSP templates from BC03 as default. Results obtained when using a grid of Maraston (2005, hereafter M05) SSP templates for different ages and metallicities will be addressed as well. For the intrinsic emission $L_{Int}$ of the black hole particle(s), we scale a luminosity-dependent template SED by the bolometric black hole luminosity given by the simulation (see Hopkins et al. 2007b). Parameters in Equation (3) that are dependent on the line of sight are subscripted with "los". To each stellar particle, the column density of hydrogen ($N_{H_{i,los}}$) and the average metallicity along the line of sight ($Z_{i,los}$) was computed for 100 viewing angles, uniformly spaced on a sphere. The optical depth is proportional to this metallicity-scaled column density, so that $A_B/N_{HI} = (Z/0.02)(A_B/N_{HI})_{MW}$ where the gas-to-dust ratio of the Milky Way equals $(A_B/N_{HI})_{MW} = 8.47 \times 10^{-22}$ cm$^2$. The wavelength dependence is adopted from an attenuation law (parameterized by the cross section $\sigma(\lambda)$). We use the Calzetti et al. (2000) reddening curve unless mentioned otherwise. The change in predicted colors when adopting the SMC-like attenuation law from Pei (1992) will be discussed as well.

## 4. SAMPLE SELECTION

Our aim is to compare the color distribution, number, and mass density of mass-limited samples of observed and simulated galaxies. We choose the mass limit such that the observed sample is reasonably complete in the considered redshift interval, even for the field with the shallowest $K_s$-band depth from which the sample was drawn. In order to optimally exploit the range in area and depth of the considered surveys, we define two mass-limited samples and divide each in two redshift bins: $1.5 < z < 2.25$ and $2.25 < z < 3$, probing a similar comoving volume. The first sample contains galaxies more massive than $\log M = 10.6$ ($M \simeq 4 \times 10^{10}\ M_\odot$) in the FIRES and GOODS-South fields. It contains 134 and 106 objects in the low- and high-redshift bins, respectively. We present the sample in Figure 1, where we plot the stellar mass of all FIRES and FIREWORKS sources that are detected above the $5\sigma$ level in the respective redshift bin against their total observed $K_s$-band magnitude. The stellar mass correlates with the $K_s$-band magnitude, but a scatter of an order of magnitude is present due to the range in redshifts and spectral types of the galaxies. The 90% completeness limit ($K_{s,tot} = 23.7$) for the GOODS-South field, which is shallower than the FIRES fields, is indicated with the dotted line. At $1.5 < z < 2.25$, no massive ($\log M > 10.6$) galaxies fainter than $K_{s,tot} = 23.7$ are found in the FIRES fields and deeper parts of the GOODS-South mosaic. The lowest $K_s$-band signal-to-noise ratio (S/N) in the massive galaxy sample is $S/N_{K_s} \simeq 9$, strongly suggesting that no incompleteness correction is needed to compute the number and mass density in the $1.5 < z < 2.25$ redshift bin. In the $2.25 < z < 3$ redshift bin, we find seven well detected massive ($\log M > 10.6$) galaxies fainter than the 90% completeness limit of GOODS-South. All of them have $5 < S/N_{K_s} < 10$, whereas the vast majority (90%) of massive galaxies with $K_{s,tot} < 23.7$ are detected above the $10\sigma$ level. Evaluating the fraction of massive galaxies fainter than $K_{s,tot} = 23.7$ in the area that is sufficiently deep to detect these sources, we estimate the completeness in the high-redshift bin to be $\sim$93%.

In order to reduce the uncertainty from cosmic variance in the derived number and mass densities, we also compose a

**Figure 1.** Relation between stellar mass and observed total $K_s$ magnitude for galaxies in the FIRES and GOODS-South fields at (a) $1.5 < z < 2.25$ and (b) $2.25 < z < 3$. The solid lines show the adopted $\log M > 10.6$ (FIRES+GOODS-South) and $\log M > 11$ (FIRES+GOODS-South+MUSYC) mass limits. The dotted line indicates the photometric limit of the GOODS-South imaging. The dashed line indicates the approximate limit for the MUSYC fields. There are few galaxies with $\log M > 10.6$ and $K_{s,tot} > 23.7$, or $\log M > 11$ and $K_{s,tot} > 22.7$. The largest incompleteness correction is needed for the highest redshift bin in the MUSYC fields. A fifth of the $\log M > 11$ galaxies would be undetected by MUSYC, as estimated from the deeper FIRES+GOODS fields.

sample including the MUSYC fields, increasing the sampled area by roughly a factor of 3.6. The shallower depth forces us to restrict the mass limit to $M > 10^{11}\ M_\odot$. The number of objects above this mass limit is 176 at $1.5 < z < 2.25$ and 71 at $2.25 < z < 3.0$. We derive the completeness in the two redshift intervals using the deeper FIRES and GOODS-South fields in Figure 1. The dashed line marks the approximate depth (90% completeness) for the MUSYC fields. None of the $1.5 < z < 2.25$ galaxies with $\log M > 11$ in the deeper FIRES and GOODS-South fields are fainter than this limit. For the $2.25 < z < 3$ bin, the fraction of massive galaxies that would be missed by MUSYC increases to 19%. In our analysis, we apply the appropriate incompleteness corrections unless stated otherwise. For each considered redshift bin and mass limit, the sample size decreases by roughly a factor of 1.5 when using M05 models.

## 5. METHODOLOGY

Large cosmological simulations with sufficient resolution to study the accretion onto SMBHs are computationally very challenging. First attempts were undertaken by Di Matteo et al. (2008), but by and large, hydrodynamical simulations
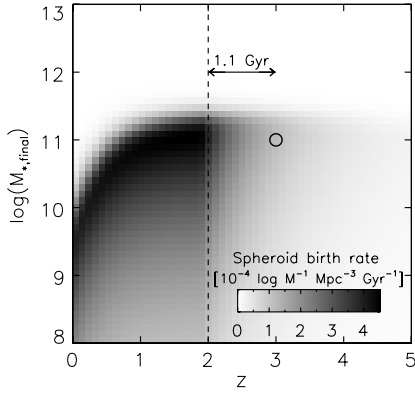

**Figure 2.** Birthrate of spheroids (in grayscale) as a function of redshift and final stellar mass as derived from the observed quasar luminosity function. The meaning of the timescale arrow and the open circle is described in the text. The model by Hopkins et al. (2006b) assumes that this birthrate equals the merger rate of galaxies. The birthrate (i.e., merger rate) reaches a maximum of $4.5 \times 10^{-4}$ log $M^{-1}$ Mpc$^{-3}$ Gyr$^{-1}$ at $z \sim 2$. As time evolves, the peak of the merger rate function shifts toward lower mass galaxies.

including a self-consistent treatment of SMBH growth have only been run with adequate resolution on binary merger systems (Springel et al. 2005a; Di Matteo et al. 2005; Robertson et al. 2006a, 2006b; Cox et al. 2006a, 2006b) or as zoom-in on overdense regions of cosmological *N*-body simulations at very high redshift $z \sim 6$ (Li et al. 2007). In order to confront observations of $1.5 < z < 3$ galaxies with the hydrodynamical simulations, we populate a model universe with the binary mergers according to a merger rate estimated from the observed quasar luminosity function following the prescription by Hopkins et al. (2006b). As a caveat, we note that this approach does not allow for a replenishment of the galaxy's gas reservoir by further accretion from the intergalactic medium (see also Sections 11.5 and 11.7). As such, it is not a full cosmological prediction by itself, but our comparison can be used to see whether the assumption that the mergers will not experience further infall leads to reasonable results.

Briefly, the conversion from quasar demographics to galaxy demographics goes as follows. From a large set of binary merger simulations, Hopkins et al. (2006a) determined the distribution of quasar lifetimes, describing the time $\frac{dt(L, L_{peak})}{d \log(L)}$ spent by a quasar of peak luminosity $L_{peak}$ in the luminosity interval $d \log(L)$. The observed quasar luminosity function simply corresponds to the convolution of this differential quasar lifetime with the birthrate $\dot{n}(L_{peak})$ of quasars with peak luminosity $L_{peak}$:

$$\Phi(L) = \int \frac{dt(L, L_{peak})}{d \log(L)} \dot{n}(L_{peak}) \, d \log L_{peak}. \quad (4)$$

Using a compilation of observed quasar luminosity functions in the hard X-rays (Ueda et al. 2003), soft X-rays (Hasinger et al. 2005), and optical (Richards et al. 2005), Equation (4) was then de-convolved to solve for $\dot{n}(L_{peak})$. The relation between peak luminosity of the quasar and the final black hole mass, derived from the same simulations, was then adopted to calculate the birthrate of black holes of a certain final mass $\dot{n}(M_{BH})$. This function was then converted to a birthrate of spheroids $\dot{n}(M_{sph})$ as a function of their final stellar mass using the SMBH–host connection $M_{BH} = 0.0012 \frac{(1+z^{2.5})}{\left(1+\left(\frac{z}{1.775}\right)^{2.5}\right)} M_{sph}$ (Hopkins et al. 2007a).

The model by Hopkins et al. (2006b) assumes that the birthrate of spheroids equals the major merger rate of galaxies.

The resulting merger rate as a function of redshift and final stellar mass is displayed with grayscales in Figure 2 (darker meaning a higher merger rate). Its redshift dependence was derived by considering observed quasar luminosity functions at a range of redshifts. The peak of the merger rate at $z \sim 2$ has a value of $4.5 \times 10^{-4}$ log $M^{-1}$ Mpc$^{-3}$ Gyr$^{-1}$. A clear trend is visible of mergers occurring in increasingly lower mass systems as we proceed in time (i.e., to lower redshifts) after this peak. If mergers are responsible for a significant part of the growth in stellar mass, this trend explains at least qualitatively the observed downsizing of star formation over cosmic time (Cowie et al. 1996).

To evaluate the postmerger (i.e., postquasar, since the merging event triggers quasar activity in the simulations) galaxy population at $z \sim 2$, we integrate the merger rate function from $z = \infty$ to 2 and over the whole stellar mass range. For example, when the integration reaches ($M_{*,final} = 10^{11} M_\odot$; $z = 3$), marked by the circle in Figure 2, we compute the photometry of a merger simulation with a final stellar mass of $10^{11} M_\odot$ at 1.1 Gyr after the peak of quasar luminosity (the time elapsed between $z = 3$ and $z = 2$). As explained in Section 3, we compute the synthetic photometry along 100 lines of sight, uniformly spaced on a sphere. The number density of galaxies at $z = 2$ with colors corresponding to the 100 lines of sight is then scaled according to the value of the merger rate function at $M_{*,final} = 10^{11} M_\odot$; $z = 3$. Finally, a mass cut is applied to guarantee an identical selection of observed and simulated galaxies (Section 11.1.2 addresses this step in more detail).

In order to predict the abundance and properties of galaxies at $z \sim 2$ that have yet to reach their peak in quasar luminosity or did not even start merging at the evaluated epoch, one can in principle integrate the merger rate function down to lower and lower redshifts. How far one integrates beyond the evaluated redshift is a rather arbitrary choice. We caution that counting galaxies long before they will contribute to the quasar luminosity function will lead to large uncertainties given their unconstrained premerger history. The typical evolution of a merger simulation is illustrated in Figure 3 where we plot the SFR, stellar mass, and rest-frame *V*-band luminosity as a function of time since the peak in quasar luminosity. We decide to integrate 700 Myr beyond the evaluated redshift, thus counting both the galaxies that are undergoing a merger-induced nuclear starburst (sometime between 0 and 200 Myr before the quasar phase) and those with star formation triggered by the first passage (sometime between 200 and 700 Myr before the quasar phase). Hereafter, we will refer to all galaxies in an evolutionary stage between 0 and 700 Myr before the quasar phase as merging galaxies. Such a prediction only counts those galaxies that will later merge and produce a quasar. Apart from predicting the abundance and properties of the postquasar population, we will thus be able to constrain how many of the massive star-forming galaxies can be accounted for by merger-induced star formation.

In the early stages of the merging process, the two progenitor galaxies may be resolved as two separate objects in the observations. We simulate this in our model by calculating the projected angular distance between the central black holes for each snapshot and viewing angle at the considered redshift. If the projected separation is larger than 1″5, the two progenitors are counted separately, each containing half the mass. For smaller projected separations, or when the black hole particles have merged, we consider the system unresolved and use the integrated properties in our model predictions. In cases where the two progenitor components are counted separately, the merger
**Figure 3.** Typical evolution of a merger simulation: (a) star formation history, (b) history of the mass build-up, and (c) evolution of the rest-frame *V*-band luminosity. The dotted line indicates when the peak in quasar luminosity is reached. For a detailed description of the time evolution in these and other parameters (e.g., accretion rate, quasar luminosity, extinction), we refer the reader to Hopkins et al. (2006a).

contributes twice to the number density, but with half the mass, and may therefore drop out of the mass-limited sample.

Provided the assumption of a one-to-one correspondence between quasars and major mergers is valid, the formal uncertainty in the merger rate function presented in Figure 2 originates mostly from the poorly constrained faint end of the observed quasar luminosity function, where one can assume a pure luminosity evolution or also a slope evolution. At the bright end, and therefore for our massive galaxy samples, the predictions are robust.

## 6. THE NUMBER DENSITY, MASS DENSITY, AND MASS FUNCTION OF GALAXIES WITH $\log M > 10.6$ AT $1.5 < z < 3$

Before analyzing the observed and modeled massive galaxy sample as a function of color and galaxy type, we consider the overall abundance of galaxies above $\log M > 10.6$. We computed the model number and mass density by integrating the merger rate function to 700 Myr beyond the evaluated redshift, i.e., including galaxies up to 700 Myr before the quasar phase. In Figure 4, the number and mass densities of galaxies with $\log M > 10.6$ predicted by the model (empty symbols) are compared against the abundance of observed galaxies (filled symbols) above the same mass limit. Circles indicate results using our default (BC03) SED modeling. Triangles represent the abundances derived using M05 models. The results are listed in Table 1. The spread of the empty symbols indicates the freedom allowed by the model due to the poorly constrained faint end of the quasar luminosity function.

We considered three sources of error in the observations: Poisson shot noise, cosmic variance, and selection uncertainties stemming from uncertainties in the redshift and mass estimates of individual galaxies. The black error bars in Figure 4 indicate the contribution from Poisson noise, ranging from 8% to 10%. We are more severely limited by cosmic variance. We follow the method outlined by Somerville et al. (2004) to calculate

**Figure 4.** Number and mass density of observed (filled symbols; FIRES + GOODS-S) and modeled (empty symbols) galaxies with $\log M > 10.6$ as a function of redshift. The black error bar represents the Poisson shot noise solely. The gray error bar accounts for uncertainties in redshift and mass, and a (dominating) contribution from cosmic variance. We find that both the predicted number and mass densities agree within the error bars with the observed values.

the cosmic variance as predicted from cold dark matter theory for a population with unknown clustering as a function of its number density and the probed comoving volume of the sample. The resulting contribution to the error budget is 29% for the $1.5 < z < 2.25$ and 30% for the $2.25 < z < 3$ redshift bin. Finally, the uncertainties in the individual redshift and mass determinations propagate into the number and mass density of massive high-redshift galaxies. We estimate the contribution to the total error budget from Monte Carlo simulations. We constructed 100 mock catalogs for the FIRES and GOODS-South fields by perturbing the fluxes so that 68% of the perturbed values lie within the $1\sigma$ errors. We then repeated the computation of photometric redshifts and other derived properties such as stellar mass.

After constructing the 100 mock catalogs, we apply the same sample selection (redshift interval, $\log M > 10.6$) and compute the number and mass density for each of them. The lower and upper limits comprising 68% of the distribution of mock number and mass densities were added in quadrature to the uncertainty from Poisson shot noise and cosmic variance, shown with the gray error bar in Figure 4. The uncertainty in the number density propagating from redshift and mass uncertainties for individual objects amounts to 5% and 10% for the low- and high-redshift bins, respectively. The contribution to the uncertainty in the mass density is 6% and 14% for the low- and high-redshift bins, respectively. We conclude that, even with the 138 arcmin$^2$ area of our combined deep fields, cosmic variance is still the limiting factor for the determination of the number and mass density of massive high-redshift galaxies. Furthermore, we note that the number and mass densities systematically drop by a factor of 1.5 and 1.7, respectively, when using M05 models.

Given these uncertainties, Figure 4 shows a good agreement between the model number and mass density for the population of massive ($\log M > 10.6$) galaxies as a whole and the observations. Plotting the mass function for the observations (red histogram) and the model (dark-gray polygon) in Figure 5, we find that the comparable abundance of observed and modeled galaxies still holds when studied as a function of galaxy mass. With lighter gray polygons, we illustrate the model

**Table 1**
Number and Mass Densities for Massive Galaxies

| Type | Mass Limit | Redshift | Observations[a] | | Model Prediction[b] | |
|---|---|---|---|---|---|---|
| | $(M_\odot)$ | | $n$ $(10^{-4}\ \mathrm{Mpc}^{-3})$ | $\rho_*$ $(10^7\ M_\odot\ \mathrm{Mpc}^{-3})$ | $n$ $(10^{-4}\ \mathrm{Mpc}^{-3})$ | $\rho_*$ $(10^7\ M_\odot\ \mathrm{Mpc}^{-3})$ |
| All | $4 \times 10^{10}$ | $1.5 < z < 2.25$ | $4.0^{+1.3}_{-1.3}$ | $3.8^{+1.3}_{-1.2}$ | $4.8 - 5.5$ | $5.4 - 6.0$ |
| All | $4 \times 10^{10}$ | $2.25 < z < 3$ | $3.3^{+1.1}_{-1.2}$ | $2.8^{+0.9}_{-0.9}$ | $1.9 - 2.2$ | $1.9 - 2.2$ |
| Quiescent | $4 \times 10^{10}$ | $1.5 < z < 2.25$ | $1.2^{+0.5}_{-0.5}$ | $1.4^{+0.6}_{-0.6}$ | $2.4 - 3.9$ | $3.0 - 4.8$ |
| Quiescent | $4 \times 10^{10}$ | $2.25 < z < 3$ | $1.0^{+0.4}_{-0.5}$ | $0.8^{+0.3}_{-0.4}$ | $0.4 - 1.1$ | $0.4 - 1.3$ |
| Star-forming | $4 \times 10^{10}$ | $1.5 < z < 2.25$ | $2.8^{+1.1}_{-1.0}$ | $2.5^{+1.0}_{-0.9}$ | $1.5 - 2.7$ | $1.2 - 2.6$ |
| Star-forming | $4 \times 10^{10}$ | $2.25 < z < 3$ | $2.3^{+0.9}_{-1.0}$ | $2.0^{+0.8}_{-0.8}$ | $1.0 - 1.7$ | $0.8 - 1.7$ |
| Quiescent | $10^{11}$ | $1.5 < z < 2.25$ | $0.7^{+0.2}_{-0.2}$ | $1.1^{+0.3}_{-0.3}$ | $1.3 - 2.2$ | $2.3 - 3.6$ |
| Quiescent | $10^{11}$ | $2.25 < z < 3$ | $0.2^{+0.1}_{-0.1}$ | $0.3^{+0.2}_{-0.1}$ | $0.2 - 0.6$ | $0.3 - 1.0$ |
| Star-forming | $10^{11}$ | $1.5 < z < 2.25$ | $0.8^{+0.3}_{-0.2}$ | $1.2^{+0.5}_{-0.4}$ | $0.3 - 0.9$ | $0.5 - 1.5$ |
| Star-forming | $10^{11}$ | $2.25 < z < 3$ | $0.5^{+0.3}_{-0.2}$ | $0.8^{+0.7}_{-0.4}$ | $0.2 - 0.6$ | $0.3 - 1.0$ |
| $SFR/M < 1/t_{\mathrm{Hubble}}$ | $4 \times 10^{10}$ | $1.5 < z < 2.25$ | $1.3^{+0.7}_{-0.6}$ | $1.5^{+0.7}_{-0.7}$ | $3.4 - 3.9$ | $4.2 - 4.8$ |
| $SFR/M < 1/t_{\mathrm{Hubble}}$ | $4 \times 10^{10}$ | $2.25 < z < 3$ | $0.6^{+0.9}_{-1.2}$ | $0.5^{+0.6}_{-0.9}$ | $1.0 - 1.2$ | $1.3 - 1.5$ |
| $SFR/M > 1/t_{\mathrm{Hubble}}$ | $4 \times 10^{10}$ | $1.5 < z < 2.25$ | $2.5^{+1.0}_{-0.9}$ | $2.2^{+0.9}_{-0.8}$ | $1.5 - 1.5$ | $1.1 - 1.2$ |
| $SFR/M > 1/t_{\mathrm{Hubble}}$ | $4 \times 10^{10}$ | $2.25 < z < 3$ | $2.6^{+1.3}_{-1.0}$ | $2.1^{+1.3}_{-1.0}$ | $0.9 - 0.9$ | $0.7 - 0.7$ |

**Notes.**

[a] The error bars in the observed densities account for Poisson noise, cosmic variance, and the uncertainties in redshift, rest-frame color, and mass of the individual galaxies. They do not account for the systematic dependence on the stellar population synthesis code used to derive the stellar masses (values given here are for BC03), nor was the systematic uncertainty in the conversion from 24 $\mu$m to SFR (of the order of 1 dex) included in the results for the sample selected on $SFR/M$.

[b] The range in model densities indicates a crude estimate of the size of uncertainties in the merger rate function and the dependence on the choice of attenuation law and stellar population synthesis code to compute the synthetic photometry.

**Figure 5.** Mass function of observed (red histogram; FIRES + GOODS-S) and modeled (gray polygons) galaxies with $\log M > 10.6$ at redshift $1.5 < z < 2.25$ (top panel) and $2.25 < z < 3.0$ (bottom panel). Merger remnants alone ($t > t_{\mathrm{QSO}}$) cannot account for the total population of observed galaxies above the same mass limit. A better consistency with the observations is reached when integrating the merger rate function to include galaxies up to 700 Myr before the quasar phase.

(A color version of this figure is available in the online journal.)

prediction when including only galaxies up to 200 Myr before the merger ($t > -200$ Myr) or only merger remnants ($t > t_{\mathrm{QSO}}$). The width of the polygons reflects the uncertainty in the merger rate function. We conclude that merger remnants alone cannot account for the entire observed massive galaxy population at $1.5 < z < 3$. However, including galaxies with

merger-triggered star formation, the mass function predicted by the model is in good agreement with the observations. This encourages a more detailed investigation of the properties of observed and simulated massive galaxies.

A detailed study of the stellar mass function of observed galaxies from $z = 4.0$ to $z = 1.3$, as well as a comprehensive analysis of random and systematic uncertainties, is presented by Marchesini et al. (2008). We note that our abundance estimates of observed massive galaxies are consistent with those derived from the work of these authors. Also, our cosmic variance estimates are consistent with those empirically derived by Marchesini et al. (2008), who find that cosmic variance is the dominant source of random uncertainties at $z < 2.5$.

## 7. THE COLOR DISTRIBUTION OF GALAXIES WITH $\log M > 10.6$ AT $1.5 < z < 3$

### 7.1. The $U - V$ Color Distribution

First, we consider the optical color distribution of our sample of FIRES and FIREWORKS galaxies with $M > 4 \times 10^{10}\ M_\odot$. A histogram of their rest-frame $U - V$ colors is plotted in red in Figures 6(a) and (b) for the low- and high-redshift bins, respectively. No corrections for incompleteness were applied here, but we remind the reader that those are negligible for the low-redshift bin and 7% only for the high-redshift bin.

Massive high-redshift galaxies span a broad $U - V$ color range. In both redshift bins, the median color is $U - V = 1.5$ and 68% of the galaxies lie within the $1.1 < U - V < 1.8$ interval.

It is interesting to consider whether the simulated descendants and progenitors of quasars (or rather quasar hosts) above the same mass limit show colors that are similar and come in numbers comparable to those of the observed massive galaxy sample. In this section, we focus mainly on the first question, but note in passing that we show the predicted color distribution scaled to the same solid angle as probed by the FIRES and FIREWORKS observations. The filled gray histograms show
**Figure 6.** Rest-frame $U - V$ color distribution of observed galaxies with masses above $\log M = 10.6$ in the FIRES and GOODS-South fields (solid and dashed line for masses based on BC03 and M05, respectively) for the redshift intervals (a) $1.5 < z < 2.25$ and (b) $2.25 < z < 3$. Filled histograms are the predicted $U - V$ color distribution of merging and postquasar galaxies, scaled to the same solid angle as the observations. The light gray top of the model histogram reflects the uncertainty in the merger rate function. For a given redshift interval, the model predictions in the three panels give an indication of the uncertainty in the synthetic photometry induced by the choice of attenuation law (Calzetti et al. 2000 vs. the SMC curve from Pei 1992) and the choice of stellar population synthesis code (BC03 vs. M05). Overall, the predicted color distribution coincides with that of the observed massive galaxy sample, with roughly equal numbers. The red tail of the observed color distribution at $2.25 < z < 3$ is not reproduced by the modeled merger and postquasar population.

(A color version of this figure is available in the online journal.)

the synthetic photometry of merger simulations in either their postquasar phase or in a phase of at most 700 Myr before their peak in quasar luminosity. The numbers at each color are derived from the observed quasar luminosity function by integrating the merger rate function from $z = \infty$ to 700 Myr beyond the evaluated redshift as described in Section 5. The colors of different evolutionary phases will be discussed separately in due time. The difference between the dark and light gray histogram reflects the uncertainty in the merger rate function, itself due to uncertainties in the observed quasar luminosity function. Apart from uncertainties in the merger rate function, uncertainties in the synthetic photometry for a given simulation snapshot contribute to the total error budget of the model predictions. To translate the simulated properties such as age, mass, and metallicity of the stellar particles to observables, we make use of a stellar population synthesis code to compute the intrinsic colors and assume an attenuation law to calculate the dimming and reddening by dust. We investigate the dependence on attenuation law empirically by computing the synthetic photometry using a Calzetti et al. (2000) reddening curve and the SMC-like reddening curve from Pei (1992). We note that the synthetic colors derived with the Milky-Way-like attenuation curve by Pei (1992) lie in between those produced by the two reddening curves considered here. This is demonstrated by Wuyts et al. (2009). Similarly, we test the dependence on adopted stellar population synthesis templates empirically by computing the synthetic photometry based on a grid of BC03 SSPs and based on a grid of SSPs by M05.

We note that the choice of attenuation law has a minor effect only on the $U - V$ color. The use of M05 templates gives the simulated galaxies a slightly redder color. Overall, the same conclusion can be drawn independent of the choice of attenuation law or stellar population synthesis code. Namely, the simulated galaxies with $\log M > 10.6$ span a color range that reaches from the bluest observed $U - V$ colors to $U - V \sim 2$. At $1.5 < z < 2.25$, the color distribution resembles remarkably well that of the bulk of the observed massive galaxies, both in shape and numbers. We apply a Kolmogorov–Smirnov (K–S)

test, and find that the observed and model color distributions do not differ at the 5% significance level. At $2.25 < z < 3$, the predicted model colors do not reach the reddest $U - V$ colors of observed galaxies above the same mass limit. A K–S test indicates a formal difference between the observed and model color distribution. We do note, however, that the observed sources with $U - V > 2$ have fairly large uncertainties in their rest-frame optical color measurement, and are nearly all consistent within $1\sigma$ with an actual color of $U - V < 2$. The good overall correspondence between the observed and modeled optical color distributions gives a first indication that the number of massive postquasar galaxies plus the number of galaxies in the process of merging at $1.5 < z < 3$ as expected from the observed quasar luminosity function may account for a large fraction of the observed massive galaxy population in that redshift range.

### 7.2. The $V - J$ Color Distribution

Turning to longer wavelengths, we now compare the $V - J$ colors predicted for mergers and merger remnants (i.e., postquasars) with masses above $\log M = 10.6$ to the color distribution of observed galaxies in the same redshift interval and above the same mass limit (Figure 7).

Again, the color distribution of our observed massive galaxy sample has a large range of colors, reaching from $V - J = 0.5$ to $V - J = 2.5$. We measure a median color of $V - J = 1.5$ and 1.3 for the low- and high-redshift bins, respectively. The central 68% intervals are $1.1 < V - J < 1.9$ and $0.9 < V - J < 1.8$.

As for the $U - V$ color distribution, we find that the adopted attenuation law has only a minor influence on the model color distribution, reaching at most shifts of 0.2 mag toward redder $V - J$ colors when the SMC-like reddening curve from Pei (1992) is used instead of the Calzetti et al. (2000) attenuation law. Comparing the model $V - J$ color distribution derived from BC03 or M05 templates immediately shows that the predictive power of the merger model is strongly hampered by the uncertainties in the rest-frame NIR wavelength regime that today's stellar population synthesis codes are facing. In
**Figure 7.** Rest-frame $V - J$ color distribution of observed and simulated galaxies with masses above $\log M = 10.6$ for the redshift intervals (a) $1.5 < z < 2.25$ and (b) $2.25 < z < 3$. Style as in Figure 6. The model $V - J$ color distribution is only poorly constrained due to the uncertainties at NIR wavelengths in the stellar population synthesis codes. Nevertheless, we can conclude that there exist massive galaxies with redder $V - J$ colors than those of modeled merging and postquasar galaxies.
(A color version of this figure is available in the online journal.)

the low- and high-redshift bins, the median $V - J$ color of the model distribution is 0.4 and 0.5 mag redder when using M05 than when using BC03. One of the main differences between the BC03 and M05 templates is the treatment of thermally pulsating AGB stars. M05 uses the fuel consumption approach instead of the isochrone synthesis approach that BC03 follow. In addition, the two models construct the synthetic populations using different stellar isochrones. The combined effect is that M05 finds significantly larger NIR luminosities for SSPs at ages between 0.2 and 2 Gyr than BC03. For an in-depth discussion of the differences between the two codes, we refer the reader to Maraston (2005) and Maraston et al. (2006). It is worth stressing that, irrespective of whether the BC03 or M05 stellar population synthesis code is used, the red ($V - J > 1.8$) tail of the observed distribution has no counterparts in the modeled color distribution of merging and postmerger galaxies. Conversely, an excess of galaxies is found at blue ($V - J \sim 0.9$) or intermediate ($V - J \sim 1.4$) optical-to-NIR colors for the BC03 and M05 model color distributions, respectively. A K–S test shows that the difference between the distributions is significant at the 99.99% level. Uncertainties in the derived rest-frame colors of observed galaxies are unlikely to be responsible for the offset.

### 7.3. $U - V$ Versus $V - J$ Color–Color Distribution

#### 7.3.1. Quiescent Red Galaxies

Recently, a diagnostic color–color diagram of observer-frame $I-K$ versus $K - [4.5\mu m]$ has been proposed by Labbé et al. (2005) to distinguish three basic types of $z > 2$ galaxies. The rest-frame equivalent of this diagram, $U - V$ versus $V - J$ (hereafter UVJ) allows a comparison of galaxies over a wider redshift range (Wuyts et al. 2007; Williams et al. 2009; I. Labbé et al. 2009, in preparation). First, there are galaxies with relatively unobscured star formation, such as the majority of Lyman break galaxies (Steidel et al. 2003) and their lower redshift BX/BM analogs (Adelberger et al. 2004). They typically have young ages and low reddening values, resulting in blue colors, both in the rest-frame optical and in the rest-frame optical-to-NIR. Second, there is a population of star-forming galaxies with much redder colors, due to the presence of dust. Their intrinsic (unobscured) colors are similar to those of Lyman break galaxies, but they

are driven toward redder $U - V$ and redder $V - J$ colors along a dust vector whose slope depends on the nature and distribution of the dust (see, e.g., Wuyts et al. 2009). Finally, a population of galaxies with red $U - V$ colors is present at $z \sim 2$ whose SED is well matched by that of a passive or quiescently star-forming galaxy at an older age. Their $V - J$ colors are relatively blue compared to those of dusty starbursts at the same optical color.

I. Labbé et al. (2009, in preparation) designed a color criterion to select the quiescent red galaxies based on their rest-frame $U$, $V$, and $J$ photometry. The selection window is defined as follows:

$$U - V \geqslant 1.3, \quad V - J \leqslant 1.6, \quad U - V \geqslant 0.9(V-J)+X, \quad (5)$$

where $X$ is 0.31 and 0.4 for our low- and high-redshift bins, respectively.

The validity of this selection criterion was confirmed by the fact that galaxies within the UVJ box generally have low MIPS-based specific SFRs (I. Labbé et al. 2009, in preparation). Conversely, MIPS detected galaxies at $z \sim 2$, suggesting dust-enshrouded star formation, tend to lie redward of the wedge. We draw the wedge in Figure 8 and indicate the location of all galaxies with $\log M > 10.6$ in the FIRES and GOODS-South fields in the color–color diagram. Red circles mark the objects that satisfy Equation (5). The upper panels show the observed sample with BC03-based masses above $\log M > 10.6$, whereas in the bottom panels the mass limit was applied to the M05-based stellar mass estimates.

We also present a binned representation of the model color–color distribution of postquasar galaxies only in Figure 8. The panels correspond to the $1.5 < z < 2.25$ and $2.25 < z < 3$ redshift bins, and model photometry derived from BC03 and M05 templates, respectively. The color–color distribution computed with the SMC-like reddening curve from Pei (1992) instead of the Calzetti et al. (2000) law is not plotted, but looks very similar. In the age range of 0.3–1 Gyr, a dust-free SSP template of M05 has redder $V - J$ colors than a model of BC03 due to a different implementation of the thermally pulsing asymptotic giant branch (TP-AGB) phase (e.g., Maraston et al. 2006). Summing over all stellar particles (each treated as an SSP) of the simulated poststarburst (postquasar) galaxies, this produces the shift toward redder integrated $V - J$ colors in panels (c) and (d) with respect to panels (a) and (b).
**Figure 8.** Model rest-frame $U - V$ vs. $V - J$ color–color distribution of simulated galaxies with log $M > 10.6$ that have had a merger and quasar phase in their past (grayscales), with a darker intensity indicating a larger number of postquasars. Observed galaxies above the same mass limit in the FIRES and GOODS-South fields are overplotted. Red symbols mark the galaxies that satisfy the quiescent galaxy criterion, the selection window of which is marked by the red wedge. A notable difference between the synthetic photometry derived using the BC03 and M05 stellar population synthesis code is the redder $V - J$ color in the latter case. Recognizing this uncertainty in the model prediction, we can still conclude that the predicted color distribution of postquasars roughly coincides with that of quiescent red galaxies.

(A color version of this figure is available in the online journal.)

In all realizations of the synthetic photometry, the predicted color–color distribution of the postquasar population coincides more or less with the region of color–color space selected by the quiescent galaxy criterion. As a control sample, we analyzed a set of disk simulations, identical in initial conditions to the merger progenitors, but left to evolve in isolation instead of undergoing a violent merger process. Due to the lack of new gas accretion, these simulated galaxies also reach phases of low specific SFR (SFR/$M$ < 1/$t_{\text{Hubble}}$). However, the vast majority of these evolved disk galaxies have synthetic colors that place them outside the quiescent galaxy selection window, in a region of color–color space where only actively star-forming galaxies are found in the observations. We conclude that an abrupt quenching of the star formation is required to reproduce the properties of observed quiescent galaxies at high redshift. Dissipative mergers involving AGN feedback seem to be a promising mechanism.

### 7.3.2. Star-forming Galaxies

A significant fraction (∼two-thirds) of the observed massive galaxy population at $1.5 < z < 3$ has colors located outside the quiescent red galaxy wedge. These objects reach from blue $U-V$ colors typical for Lyman break galaxies, which are known to host relatively unobscured star formation, up to the redder optical and optical-to-NIR colors from galaxies that are believed to host heavily obscured star formation. Here, we investigate whether the predicted color–color distribution for merging galaxies that will undergo a quasar phase in less than 700 Myr can reproduce the color range of observed star-forming galaxies. Figure 9 compares the model prediction (gray scale) to the observed massive galaxy colors (blue circles for star-forming galaxies).

**Figure 9.** Model rest-frame $U - V$ vs. $V - J$ color–color distribution of simulated galaxies with log $M > 10.6$ that will undergo a quasar phase in less than 700 Myr (grayscales), with a darker intensity indicating a larger number of galaxies. Observed galaxies above the same mass limit in the FIRES and GOODS-South fields are overplotted. Blue symbols mark the galaxies that fall outside the quiescent galaxy criterion (red wedge). A notable difference between the synthetic photometry derived using the BC03 and M05 stellar population synthesis code is the redder $V - J$ color in the latter case. (a) and (b) The model colors based on BC03 are a poor match to the observed star-forming galaxies (blue symbols). The $V - J$ colors fall blueward of the observed distribution, and only the lower half of the observed $U - V$ distribution of star-forming galaxies is reproduced. (c) and (d) The model colors based on M05 give a better match in the blue $U - V$ regime, but simulated objects with $V - J \gtrsim 1.6$ are nearly absent.

(A color version of this figure is available in the online journal.)

As could be anticipated from Section 7.2, the model photometry does not reproduce the colors of observed dusty star-forming galaxies ($U - V > 1.3$ and outside the quiescent red galaxy wedge). We note that our control sample of disk galaxies evolving in isolation do not reach the red optical-to-NIR colors of observed dusty starbursts either during their actively star-forming lifetime.

At bluer $U-V$, the synthetic photometry based on M05 templates gives a decent match to the observations, whereas the BC03 colors in combination with a Calzetti et al. (2000) attenuation law are offset by a few tenths of a magnitude toward bluer $V - J$.

## 8. SPECIFIC STAR FORMATION RATE AS A FUNCTION OF STELLAR MASS

So far, we have compared the synthetic colors of merging and postquasar galaxies with those of observed star-forming and quiescent galaxies, respectively. The separation between star-forming and quiescent galaxies for our observed galaxies was based on their location in the UVJ diagnostic diagram. As an independent check, we now use the UV + 24 $\mu$m derived SFRs to compare the observed distribution of specific SFRs as a function of stellar mass with the distribution predicted by the merger model. The specific SFR is defined as the ratio of the SFR over the stellar mass. It equals the inverse of a mass-doubling time in the case of constant star formation. Here, we limit our sample to the GOODS-South field, where the 24 $\mu$m imaging is sufficiently deep (20 $\mu$Jy, 5$\sigma$) to obtain useful constraints on the SFRs.
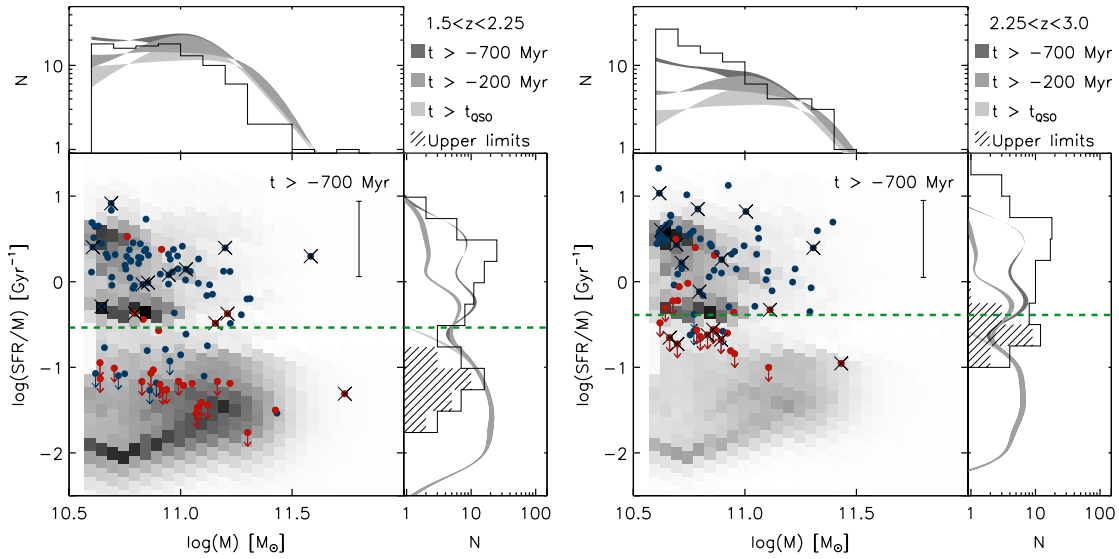

**Figure 10.** Specific SFR as a function of stellar mass for massive galaxies at $1.5 < z < 3$ in the GOODS-South field with colors falling inside (red circles) or outside (blue circles) the selection window for quiescent red galaxies. Cross symbols indicate which sources are detected in X-rays. The vertical error bar indicates the systematic error in SFR/$M$. The dashed green line marks $1/t_{Hubble}$. The model predictions are plotted with gray scale. The top and side panels show the mass and SFR/$M$ distribution, with the black histogram representing the observed sample, and the gray-scaled curves showing the model predictions for postquasars and merging galaxies up to 700, 200, and 0 Myr before the quasar phase. When integrating down to 700 Myr before the quasar phase, the predicted number density of galaxies with SFR/$M > 1/t_{Hubble}$ is 2–3 times smaller than observed, possibly (at least in part) due to AGN contribution to the 24 $\mu$m emission from which the observed SFRs were derived.

(A color version of this figure is available in the online journal.)

Figure 10 shows the binned model distribution in grayscales and overplotted are the observed massive galaxies that fall inside (red circles) and outside (blue circles) the quiescent red galaxy wedge. Upper limits are drawn for objects that were undetected by MIPS. Cross symbols mark those objects that are detected in the 1 Ms *Chandra* X-ray exposure (Giacconi et al. 2002). We caution that the 24 $\mu$m flux of these objects could have an AGN contribution. Moreover, Daddi et al. (2007b) recently found that a significant fraction (20%–30% to $K_{Vega}^{tot} < 22$, and up to $\sim$50%–60% for $M \sim 10^{11}$ $M_{\odot}$) of star-forming galaxies that are not individually detected in the X-rays shows evidence for heavily obscured AGN by the presence of an MIR flux excess. The vertical error bar indicates a conservative measure of the systematic uncertainty in the conversion from 24 $\mu$m flux to the obscured part of the SFR. The top and side panels show the distribution of masses and specific SFRs separately. With lighter polygons, we illustrate how the predicted distribution changes when integrating the merger rate function only to the evaluated redshift or 200 Myr past the evaluated redshift. The latter case includes the nuclear starburst phase, but not earlier star-forming phases.

At $1.5 < z < 2.25$, the broadband color criterion is efficient in distinguishing observed quiescent galaxies from star-forming galaxies with high specific SFRs. In the higher redshift bin, we are more limited by upper limits on the 24 $\mu$m flux. The bulk of broadband-selected quiescent galaxies at $1.5 < z < 3$ shows smaller specific SFRs than their counterparts outside the broadband selection window, although some reach values above $1/t_{Hubble}$ (dashed green line). The latter objects would double their stellar mass in less than a Hubble time if they form stars at a constant rate. Perhaps they are scattered into the UVJ box by photometric redshift uncertainties, or their SFR is overestimated.

The model SFR/$M$ distribution is composed of merger-triggered star-forming galaxies with SFR/$M > 1/t_{Hubble}$, and postquasar systems with SFR/$M < 1/t_{Hubble}$. The precise shape of the distribution at the low SFR/$M$ end depends on,

e.g., the relative orientation with which the disk progenitors were merged. However, the large difference between the star formation mode before and after the quasar phase is a robust feature of all considered simulations. The depth of the MIPS observations inhibits strong observational constraints on the distribution of individual sources at the low SFR/$M$ end, but a stacking analysis by I. Labbé et al. (2009, in preparation) reveals similarly low SFR/$M$ values ($\sim$3 $\times$ $10^{-2}$ Gyr$^{-1}$) as for simulated postquasar galaxies. As in the observations, in particular at $1.5 < z < 2.25$, there is a slight hint that the most heavily star-forming objects reside primarily at the lower masses within our mass-limited sample. Papovich et al. (2006) and Reddy et al. (2006) find that the specific SFR is inversely proportional to mass, implying that the ongoing star formation at $z \sim 2$ contributes more significantly to the mass buildup of low-mass galaxies than to high-mass galaxies.

The predicted abundance of merger-triggered nuclear starbursts, occurring between 0 and 200 Myr before the quasar phase, seems to be insufficient to account for all observed massive galaxies with high specific SFRs (SFR/$M > 1/t_{Hubble}$). When including earlier phases of star formation induced by the merging event (up to 700 Myr before the quasar phase), we find that the observed number density of galaxies with SFR/$M > 1/t_{Hubble}$ is twice as large as predicted by the model. Part of this offset may be due to possible AGN contributions to the 24 $\mu$m emission from which the SFRs were derived (see, e.g., Daddi et al. 2007b). Alternatively, this might indicate that not all star-forming galaxies can be accounted for by the considered merger/quasar driven model for galaxy evolution.

## 9. THE NUMBER AND MASS DENSITY OF MASSIVE GALAXIES AT $1.5 > z > 3$: ANALYSIS BY TYPE

We now proceed to quantify the observed and modeled number and mass densities of different types of massive galaxies at $1.5 < z < 3$. As before, the model prediction was derived by

integrating the merger rate function to include all galaxies that once contributed to the observed quasar luminosity function or will do so in less than 700 Myr. From this, we extracted six samples using the criteria discussed in Sections 7.3 and 8. Four are based on the UVJ diagnostic diagram: galaxies above $\log M > 10.6$ (or $\log M > 11$) with broadband colors satisfying the quiescent red galaxy criterion (Equation (5), Section 9.1), and galaxies above $\log M > 10.6$ (or $\log M > 11$) that do not satisfy Equation (5) (Section 9.2). Furthermore, we use the MIPS-based specific SFRs to independently address the abundance of relatively quiescent ($SFR/M < 1/t_{\text{Hubble}}$, Section 9.1) and actively star-forming ($SFR/M > 1/t_{\text{Hubble}}$, Section 9.2) galaxies above $\log M = 10.6$. The $\log M > 11$ samples allow us to include the larger but shallower MUSYC survey in the comparison. In each case, we impose an identical selection criterion on the observed sample of galaxies.

### 9.1. The Number and Mass Density of Massive Quiescent Red Galaxies

Having established the similarity in colors of the model postquasar population and the observed quiescent red galaxy population above the same mass limit, we now turn to a comparison of their number and mass densities. Our aim is to constrain the fraction (in number and mass) of massive quiescent red galaxies at redshifts $1.5 < z < 3$ that descendants of merger-triggered quasars can account for.

In order to do this, we selected the observed and modeled galaxies with $\log M > 10.6$ that lie inside the wedge defined by Equation (5) and compute the number and mass density for the probed comoving volume of $\sim 3.5 \times 10^5$ Mpc$^3$ in each redshift bin. The resulting number and mass densities are plotted as a function of central redshift of the redshift bin in Figure 11(a). The filled circles and triangles indicate the observed number and mass density of quiescent red galaxies above $\log M = 10.6$ using BC03- and M05-based stellar masses, respectively. Their values and corresponding uncertainties are listed in Table 1. As in Section 6, the black error bars account for Poisson shot noise. The gray error bars also include selection uncertainties stemming from uncertainties in the redshift, mass, and rest-frame colors of individual galaxies, and a dominating contribution from cosmic variance. When correcting to the same IMF and mass limit, our estimates of the number density are in good agreement with those of smaller samples of galaxies by Cimatti et al. (2008) and Kriek et al. (2008) that are spectroscopically confirmed to be quiescent.

The empty symbols in Figure 11(a) indicate the predicted number and mass density of galaxies with $\log M > 10.6$ at $1.5 < z < 2.25$ and $2.25 < z < 3$ whose synthetic photometry places them within the selection wedge for quiescent red galaxies. Ninety-five percent of these modeled galaxies are in a postquasar phase of their evolution. The different empty symbols represent predictions derived with the BC03 and M05 stellar population synthesis codes, with the Calzetti et al. (2000) attenuation law and the SMC-like attenuation law from Pei (1992). Their spread gives a crude indication of the freedom allowed by the model. It also takes into account the uncertainty in the merger rate function used to populate our model universe with the binary merger simulations. As noted already in Section 7.3.1, synthetic photometry of postquasar galaxies based on M05 templates places part of them at redder $V - J$ than the diagonal of the UVJ box, even though their sSFRs are low ($10^{-2}$ to $10^{-0.5}$ Gyr$^{-1}$). This explains why

the M05-based model predictions in Figure 11(a) are lower than those based on our default BC03 models. We therefore consider the BC03-based model predictions of the quiescent galaxy abundance as the most reliable.

We find that the model predicts a number density of quiescent galaxies at $z \sim 1.9$ that is 2.5 times larger and a mass density that is 3 times larger than observed. At $z \sim 2.6$, the model and observations are consistent within the error bars. In other words, if anything, assuming a one-to-one correspondence between quasars and gas-rich mergers, the model by Hopkins et al. (2006b) overpredicts the abundance of merger remnants (i.e., postquasar galaxies) at $1.5 < z < 3$. The model predicts an increase by a factor of 3.5 in the number and mass density for massive postquasar galaxies in the 1 Gyr that passed between $z = 2.6$ and $z = 1.9$. The observed sample seems to suggest less evolution (a factor of 1.2 in number density and 1.8 in mass density), and is even formally consistent with a non-evolving number and mass density over the considered redshift range.

In order to reduce the effect of cosmic variance, we now include the MUSYC fields in our analysis, increasing the area by a factor of 3.6 and reducing the cosmic variance for a given mass limit with a similar factor. However, this goes at the cost of depth: the 90% completeness limit for the MUSYC fields is 1 mag shallower than for GOODS-South. Consequently, we are restricted to a sample limited at $M > 10^{11}\ M_\odot$, even then requiring a 19% correction for incompleteness in the $2.25 < z < 3$ bin. Since cosmic variance is larger for more massive galaxies, the reduction of uncertainties due to cosmic variance with respect to the deeper FIRES+GOODS-S sample is more modest than the increase in area. Figure 11(c) shows the number and mass density of $M > 10^{11}\ M_\odot$ galaxies that fall within the quiescent red galaxy wedge, as a function of redshift for the combined FIRES, FIREWORKS, and MUSYC surveys (filled black symbols). Poisson noise is negligible for this sample. The gray error bars again account for cosmic variance and the uncertainties in redshift, rest-frame color, and mass of the individual galaxies making up the sample.

The main conclusion drawn from Figure 11(c), based on a largely independent sample, is consistent with that of Figure 11(a). Namely, a model in which every observed quasar produces a massive quiescent galaxy overpredicts the abundance of such galaxies at $1.5 < z < 3$, by a factor of 3 for the sample above $10^{11}\ M_\odot$. However, for our $\log M > 11$ sample we do find that the quiescent population grows by a similar amount (a factor of $\sim 3.5$) in model and observations between $z \sim 2.6$ and $z \sim 1.9$.

When comparing the abundance of quiescent galaxies selected by their MIPS-based $SFR/M < 1/t_{\text{Hubble}}$ (Figure 11(e)), we arrive at a similar conclusion. Here, we restricted ourselves to the GOODS-S field, for which deep MIPS 24 $\mu$m data are available. If galaxies form stars at a constant rate, the adopted $SFR/M$ threshold separates galaxies that double their mass in less than a Hubble time from those that formed the bulk of their stars prior to the time of observation. We note that this threshold coincides with the minimum in the observed and modeled $SFR/M$ distribution (Figure 10). For the high-redshift ($z \sim 2.6$) bin, the presence of a bimodal $SFR/M$ distribution could not be observationally confirmed or ruled out due to the larger upper limits on individual $SFR/M$ measurements. As in Figure 11(a), we find the model number and mass density to be larger than observed, by a factor of 2.5 and 3, respectively.

Possibly, our results suggest that part of the quasar-descendants are rejuvenated, e.g. by new gas infall fueling
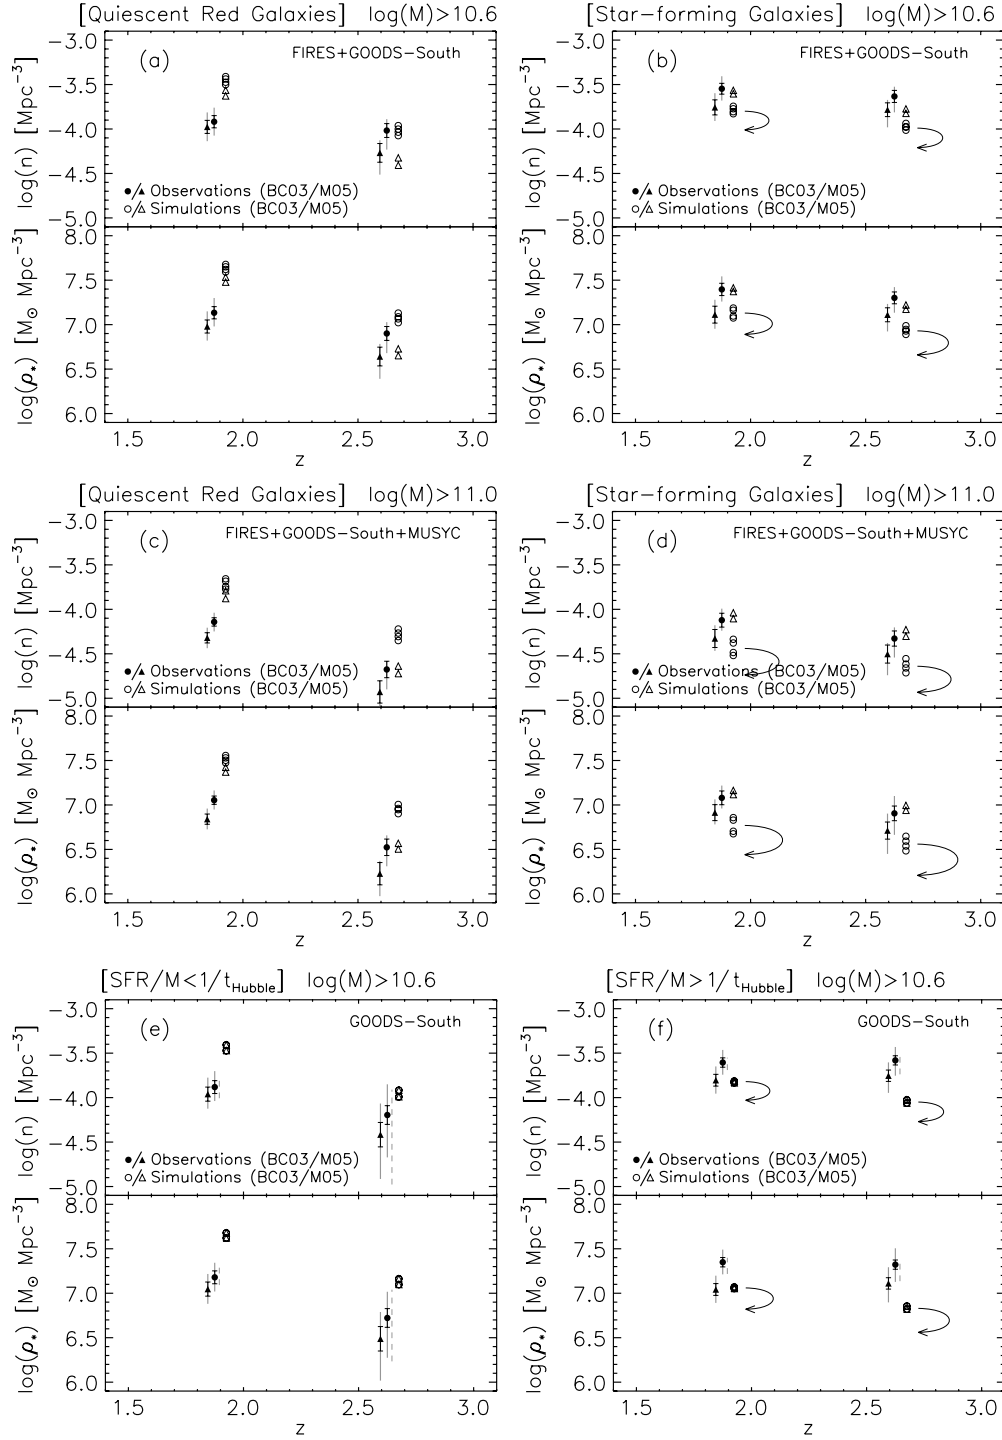

**Figure 11.** Number and mass density of observed (filled symbols) and modeled (empty symbols) massive galaxies as a function of redshift above the same mass limit and satisfying the same selection criterion. The black error bar represents the Poisson shot noise solely. The gray error bar accounts for uncertainties in redshift, mass, and rest-frame colors and a (mostly dominating) contribution from cosmic variance. The dashed error bars in panels (e) and (f) reflect the systematic uncertainty in the SFR. Arrows in panels (b), (d), and (f) indicate how the model results change when including the effect of mass underestimates in the SED modeling of star-forming galaxies. We consider six samples: (a) quiescent red galaxies with $\log M > 10.6$ in FIRES+GOODS-S, (b) star-forming (nonquiescent) galaxies with $\log M > 10.6$ in FIRES+GOODS-S, (c) quiescent red galaxies with $\log M > 11$ in FIRES+GOODS-S+MUSYC, (d) star-forming galaxies with $\log M > 11$ in FIRES+GOODS-S+MUSYC, and finally galaxies with (e) $\mathrm{SFR}/M < 1/t_{\mathrm{Hubble}}$ or (f) $\mathrm{SFR}/M > 1/t_{\mathrm{Hubble}}$ and $\log M > 10.6$ in GOODS-S. We find that the model tends to overpredict the number of quiescent and underpredict the number of actively star-forming galaxies by at most a factor of 3.

recurrent star formation. Large cosmological simulations including a prescription for AGN feedback, such as undertaken by Di Matteo et al. (2008), but with a resolution comparable to the binary merger simulations presented here are necessary to investigate such scenarios.

We should also bear in mind that the evolution of the $M_{\mathrm{BH}}-M_*$ relation and its scatter with redshift is only poorly constrained. Since this relation is used to translate observed quasar demographics into galaxy demographics (see Section 5), an uncertainty of a factor of a few in $M_{\mathrm{BH}}-M_*$ might resolve the

offset in abundance as well. Finally, we caution that beaming effects at the bright end of the quasar luminosity function might complicate the methodology described in Section 5.

### 9.2. The Number and Mass Density of Massive Star-forming Galaxies

Following identical procedures as outlined above, we analyze the number and mass density of massive galaxies with colors outside the quiescent red galaxy wedge in Figure 11(b). Again, we used a Monte Carlo simulation to determine how many galaxies moved into or out of the selection window when perturbing their photometry within the error bars and hence changing the derived properties such as mass and rest-frame photometry.

We find massive star-forming galaxies in the observed fields to be 2.3 times more abundant in number and 2 times more in mass than massive quiescent galaxies at $1.5 < z < 3$. Their contribution to the overall number and mass density decreases slightly, to 60%, when considering our $\log M > 11$ sample (Figure 11(d)).

Given that M05-based synthetic photometry placed some of the simulated postquasar galaxies with low sSFRs in the star-forming part of the UVJ diagram, we focus on the results obtained using BC03 templates (circles). The model seems to predict that massive star-forming systems are less, rather than more, abundant than high-redshift quiescent systems above the same mass limit. Whereas the model overpredicted the quiescent number and mass density by factors of a few (Section 9.1), the abundance of the star-forming population is underpredicted by a similar amount: a factor of 1.8 at $z \sim 1.9$ and a factor of 2.2 at $z \sim 2.6$.

We now compare the abundance of actively star-forming galaxies again, using an sSFR threshold as selection criterion, rather than the rest-frame optical-to-NIR colors. Selecting galaxies with $\mathrm{SFR}/M > 1/t_{\mathrm{Hubble}}$ from FIREWORKS, we find an observed number density of $2.5 \times 10^{-4}$ Mpc$^{-3}$ and $2.6 \times 10^{-4}$ Mpc$^{-3}$ at $1.5 < z < 2.25$ and $2.25 < z < 3$, respectively (Figure 11(f)). Since we interpreted all the 24 $\mu$m emission as dust re-emission from star formation, the true number density can be lower depending on the contribution from AGN (see, e.g., Reddy et al. 2005; Papovich et al. 2006; Daddi et al. 2007b). The merger model predicts an abundance of galaxies with high specific SFRs that is 1.7 (3.0) times smaller than observed in our low (high) redshift bin. Despite the possible AGN contribution to the 24 $\mu$m emission and the large systematic uncertainty in the conversion from 24 $\mu$m to the dust-obscured contribution to the SFR (dashed line in Figure 11(f)), the different selection of actively star-forming systems produces a similar result as derived from the UVJ diagram.

Testing SED modeling on mock observations of hydrodynamic merger simulations, Wuyts et al. (2009) caution for systematic mass underestimates during phases of merger-induced star formation. As discussed in Section 11.1, accounting for such an effect would increase the offset with respect to the observed abundance, such that the merger model then accounts for one-third of the observed star-forming galaxies with $\log M > 10.6$ at $z \sim 1.9$, and a quarter at $z \sim 2.6$. This result may be consistent with recent evidence for other mechanisms than major mergers driving part of the star formation at high redshift (Daddi et al. 2007a, 2007b; Shapiro et al. 2008; Genzel et al. 2008). We note that the fraction of star-forming galaxies accounted for by the merger model decreases when only considering the short-lived ($\sim$100 Myr) starburst at final coalescence instead of counting

**Figure 12.** Relative galaxy density ($\delta$) as a function of massive ($\log M > 10.6$) $1.5 < z < 3$ galaxy to $z > 1.3$ galaxy separation ($R_s$) in the GOODS-South field. The distribution predicted by the merger model is indicated with the dashed line. At separations smaller than $1\farcs5$ (dotted line) an increasing number of galaxy pairs, if present, will be missed because they would be detected as a single object. We find a clear excess at small pair separations ($R_s < 8''$), as predicted by the merger model. A weak pair excess is also visible when only considering the distribution of separations between massive $1.5 < z < 3$ galaxies (inset panel), but the excess is much below the prediction.

all merger-triggered star-forming phases as we do by integrating the merger rate function to 700 Myr before the peak of quasar activity.

Overall, we conclude that the model abundances of massive galaxies are formally consistent with the observations. However, dividing the sample in quiescent and star-forming populations, offsets of factors 2–3 occur, with the model predictions being higher for quiescent and lower for star-forming galaxies.

## 10. PAIR STATISTICS

In our model predictions of the number and mass densities of different samples of massive galaxies, a simple criterion determines whether we use the integrated properties (color, mass, SFR) for the merging pair or treat the two progenitors as resolved systems, counting each one separately, contributing half the mass and SFR (see Section 5). Evolutionary phases, redshifts, and viewing angles for which the projected angular separation between the central SMBHs is less than $1\farcs5$ were considered unresolved. All postquasar predictions are robust against the precise form of the criterion, since by that time the two progenitors have formed one galaxy. For earlier phases, applying the criterion decreases the mass density of massive galaxies, since galaxies drop out of the mass-limited sample. The effect on the number density is less trivial. On the one hand, galaxies drop out of the mass-limited sample. On the other hand, some merging pairs contribute twice.

Here, we focus on an additional test of the merger model allowed by the fact that some of the pairs will be resolved into two objects. If a significant fraction of the massive galaxy population at $1.5 < z < 3$ is indeed related to merging events, as our analysis suggests, we expect to see an excess in the pair statistics with respect to a random distribution of galaxies on the sky.

We present the distribution of galaxy–galaxy separations in the GOODS-South field in Figure 12 (solid histogram). We decide not to include the other fields, to prevent differences

in depth from influencing the pair excess signal. The main panel shows the results from a cross-correlation of our massive ($\log M > 10.6$) galaxy sample at $1.5 < z < 3$ with the sample of all galaxies above $z > 1.3$ in the GOODS-South field, thus avoiding the risk of losing pair members that by a typical photometric redshift error were placed at some lower redshift. For each massive galaxy at $1.5 < z < 3$, we measure the distance to all $z > 1.3$ galaxies. We compute the statistic

$$\delta(R_s) = \frac{\sum_{i=1}^{j} N_i(R_s)}{\pi((R_s + \epsilon)^2 - (R_s - \epsilon)^2)}, \qquad (6)$$

where $j$ is the total number of objects in our massive galaxy sample and $N_i(R_s)$ is the number of $z > 1.3$ galaxies that lie between a distance $R_s - \epsilon$ and $R_s + \epsilon$ from galaxy $i$. For a random uniform distribution of galaxies, $\delta(R_s)$ will be flat. Figure 12 shows that for our sample of massive galaxies at $1.5 < z < 3$, this is clearly not the case. An excess of pairs at $R_s < 8''$ is visible, also when we consider the distribution of separations between members of the massive galaxy sample at $1.5 < z < 3$ only (inset panel). We note that, using the wider area UDS field, Quadri et al. (2008) found an upturn of the correlation function of DRGs at $2 < z < 3$ on similarly small scales ($\theta < 10''$). Spectroscopic relative velocity measurements are needed to assess what fraction of the small scale excess is due to bound pairs in the process of merging, and how much can be attributed to an enhanced number of projected pairs due to clustering.

From the simulations, we measured the physical separations between the two merging galaxies and computed the distribution of separation angles in arcseconds on the sky using the merger rate function (see Section 5) and assuming random viewing angles. Adding the mean value of $\delta$ as measured in the interval $30'' < R_s < 80''$, we obtain a model prediction (dashed line) that is in qualitative agreement with the cross-correlation results, but larger than the weak pair excess seen in the autocorrelation. Admittedly, the predicted distribution is subject to the orbital configuration set at the start of the simulation, an effect that is not explored in this paper.

## 11. COMMENTS AND CAVEATS

In this section, we list a number of caveats, and indicate prospects for improvements on both the model and observational side. We discuss aspects affecting the determination of galaxy abundances as well as a number of possible reasons for the discrepancy between the synthetic and observed colors of massive star-forming galaxies. Future investigations along these lines will help to further test the merger model.

### 11.1. Simulating the Observing Procedure

#### 11.1.1. Color Gradients

First, it is possible that the colors of observed and modeled galaxies are in fact in agreement, but that a discrepancy was found because we did not simulate the whole observing procedure. The observed optical-to-NIR colors are measured on PSF-matched images within apertures of size $1''$ to $2''$. The IRAC photometry was performed within apertures of $3''$ diameter, and scaled to the smaller color aperture assuming all sources had a flat $K_s$–IRAC color profile (see Wuyts et al. 2008). The synthetic colors instead were based on integrated photometry of all stellar particles, irrespective of their distance to the galaxy center. The

**Figure 13.** Simulated rest-frame $U - V$ and $V - J$ colors before (blue), during (green), and after (red) a merger that ends with $M_{*,\text{final}} = 1.2 \times 10^{11} M_\odot$ as function of radius in which the color was measured. The height of the polygons indicates the range of colors for the same snapshot, as seen from different angles. Aperture sizes for the optical-to-NIR ($1'' <$ diameter $< 2''$) and IRAC photometry ($3''$ diameter) of real galaxies are marked in gray. Color gradients are present with the galaxy core being redder than the outskirts, particularly during the merger-driven nuclear starburst (green).

(A color version of this figure is available in the online journal.)

presence of a color gradient with redder emission in the central regions of the galaxies could therefore induce an offset in colors in the observed direction.

In Figure 13, we investigate the presence of color gradients for three snapshots (before, during and after the merger) of a simulation with final stellar mass $M_{*,\text{final}} = 1.2 \times 10^{11} M_\odot$. The color measured within a radius $r$ is plotted as a function of that radius. The polygon for a given snapshot illustrates the range in colors as we view the galaxy from different angles. The size of the apertures used for the observations is indicated for reference.

A color gradient is clearly present in all three phases, with the color getting progressively bluer as we increase the aperture size. The gradient is most pronounced during the merger event, and more so for $V - J$ than for $U - V$. During the nuclear starburst (green polygon), the difference (for a $1''.5$ diameter aperture) amounts up to 0.15 mag in $U - V$. Given that our $V - J$ estimates were effectively derived from $3''$ diameter apertures, a more sophisticated simulation of the observing procedure could redden the $V - J$ colors by up to 0.1 mag. For a given aperture size, the color difference between the aperture and integrated photometry also increases as we consider simulations of larger mass. For example, for a merger that is five times more massive than that shown in Figure 13, we find $(U - V)_{d=1''.5} - (U - V)_{\text{total}}$ reaches up to 0.25 mag and $(V - J)_{d=3''} - (V - J)_{\text{total}}$ up to 0.6 mag.

We note that, since color apertures varied from object to object in the observations, incorporating the details of the observing procedure in our comparison is not straightforward. Moreover, it would require a proper treatment of smearing by the PSF, which was not applied in Figure 13. Nonetheless, our analysis indicates that color profiles are present in various degrees during different phases of the merger scenario, and can contribute to the photometric differences between simulated and real galaxies. A study of color profiles for high-redshift galaxies of different types, such as will be enabled by the high-resolution imaging with WFC3 on board the *Hubble Space Telescope* (*HST*), will

provide additional constraints on the role of mergers in galaxy evolution.

### 11.1.2. Accounting for Biases in SED Modeling

In comparing abundances of modeled and observed galaxies, it is critical to apply identical selection criteria to both samples. In this paper, we work with mass-limited samples, where the stellar mass of modeled galaxies is known from the simulation output, and that of the observed galaxies is derived by fitting stellar population synthesis templates to their multiwavelength SED. Wuyts et al. (2009) tested the performance of the latter method by computing mock high-redshift observations of the same simulations as used in this paper, feeding them to the same SED modeling procedure as described in Section 2.3, and comparing the derived masses with the true values known from the simulation output. The mass estimates of merger remnants are very robust. However, during phases of merger-induced star formation systematic mass underestimates of 0.1–0.2 dex occur, with a tail toward more severe underestimates. We repeated our comparison of galaxy abundances, not using the true mass of the modeled galaxies but the value derived from fitting their virtually observed SEDs. As expected from the results by Wuyts et al. (2009), the modeled abundance of massive quiescent galaxies remains nearly unaffected. A significant fraction of simulated star-forming galaxies drops out of the mass-limited sample, reducing the modeled number density by a factor of 1.6. The mass density decreases by a factor of 1.8. The shifts in number and mass density when including the effects of mass underestimates of star-forming galaxies in SED modeling are indicated with arrows in Figure 11. We conclude that, accounting for biases in SED modeling, the merger model predicts that merger-induced star-forming galaxies above $\log M > 10.6$ can account for one-third (quarter) of the total observed massive star-forming population at $z \sim 1.9$ (2.6). Similar merger fractions among high-redshift star-forming galaxies are found by kinematic studies of the SINS survey (Shapiro et al. 2008).

### 11.2. Dependence on Stellar Population Synthesis and IMF

As pointed out in Section 7.2, the predicted rest-frame NIR luminosities for an SSP of a given mass are brighter for the M05 than for the BC03 stellar population synthesis code. Consequently, the mass estimates for observed galaxies with ages between 0.2 and 2 Gyr are lower by about a factor of 1.5 when modeled with M05 instead of BC03 templates. We indicated the resulting systematic uncertainties in the observed and modeled number and mass densities. We find number densities for all samples discussed in this paper to be typically two-thirds and mass densities to be ∼60% of the value obtained with BC03 masses. Whereas using M05-based masses brings the observed abundance of star-forming galaxies in agreement with the model prediction, it increases the discrepancy between model and observations for the quiescent population. Furthermore, deviations from a Kroupa (2001) IMF would change our results on number and mass densities of massive galaxies. Recently, van Dokkum (2008) and Davé (2008) presented evidence for an evolving IMF that is more weighted to high-mass stars at higher redshift. For the mass limit of $\log M > 10.6$ considered in this paper, the general trend of such an evolving IMF would be to lower the abundance of high-redshift galaxies above a certain mass limit, but is not trivial to implement since the change in mass-to-light ratio would depend on the galaxy's age. Marchesini et al. (2008) are the first to investigate the effect of bottom-light IMFs on the stellar mass function, and find that it does not merely result in a

shift. The precise shape of the stellar mass function depends on the characteristic mass of the bottom-light IMF, and can in some cases, perhaps counterintuitively, lead to abundances at the very high-mass end ($\log M > 11.5$) that exceed those derived with a standard IMF.

Concerning the discrepancy in colors, this could be due to an incorrect modeling of the stellar populations, rather than invalid assumptions at the basis of the model (i.e., the one-to-one correspondence between quasars and gas-rich mergers). Apart from the choice of stellar population synthesis code (see Section 7.2), the synthetic photometry depends on the attenuation law applied to each of the stellar particles. We note however that the use of a Milky-Way-like attenuation law from Pei (1992) leads to colors intermediate between those based on the Calzetti et al. (2000) and SMC-like (Pei 1992) attenuation laws presented in this paper. An attenuation law that is less gray than that of the SMC would be required to reproduce redder colors for dusty starburst galaxies.

Another stellar population parameter influencing the synthetic colors is the metallicity of the gas and the stars. In this paper, we adopted initial gas metallicities derived from the closed box model (Talbot & Arnett 1971) for the 80% gas fraction ($f_{gas}$) at the start of the simulation:

$$Z_{init} = -y \ln(f_{gas}), \qquad (7)$$

where $y = 0.02$ is the yield. The simulation keeps track of the subsequent evolution in the gas metallicity, and stellar metallicities are based on the metallicity of the gas out of which they form. If the gas was pre-enriched, this would boost the optical depths and redden the colors. Evidence of high ($\sim Z_\odot$) metallicities of massive high-redshift galaxies with red colors is given by van Dokkum et al. (2004). Repeating the post-processing of simulation snapshots with $1 Z_\odot$ added to the gas and stellar metallicities, we obtain colors that are 0.1–0.4 mag redder in $U - V$ and 0.1–0.9 mag redder in $V - J$. We note however that in $V - J$ the largest increase occurs for blue galaxies and the color distribution based on BC03 does not reach beyond $V - J \sim 1.8$.

### 11.3. Radiative Transfer

The fact that we find a difference between the observed and modeled $V - J$ colors of star-forming galaxies, does not necessarily mean that the merger scenario (mergers triggering starbursts and quasar activity, and leaving a quiescent remnant) should be abandoned. Neither does it have to imply a failure of the hydro simulations to realistically model such a merger event. Instead, and in fact more plausibly, it might reflect the difficulty of translating physical parameters stored in the GADGET-2 output into observables such as colors and fluxes. So far, we followed Hopkins et al. (2005) and Wuyts et al. (2009) to compute the synthetic photometry assuming the cold gas clouds have a negligible volume filling factor and ignoring the effect of scattering. In this subsection, we explore how the synthetic photometry changes when adopting the recently developed radiative transfer code SUNRISE (Jonsson 2006). SUNRISE is a polychromatic Monte Carlo code that uses a three-dimensional adaptive grid to treat arbitrary geometries of emitting and absorbing/scattering media. It self-consistently treats dust re-emission and self-absorption by iterating until the dust temperature converges. This is particularly important in the highly optically thick central regions of merging galaxies, and allows for future comparisons with longer wavelength observations by MIPS/*Spitzer*, SCUBA

(see, e.g., Narayanan et al. 2009), and the upcoming Herschel mission. The latest version (P. Jonsson et al. 2009, in preparation) includes a sophisticated photoionization code MAPPINGS and subresolution model to account for attenuation in the H II and photodissociation regions around young stars (Groves et al. 2008). Outside these birth clouds, SUNRISE follows the light traveling through the hot phase of the ISM, assuming a negligible volume filling factor of the cold phase clouds, as was done in our line-of-sight attenuation code. In addition to a different treatment of the radiative transfer (e.g., the inclusion of scattering), SUNRISE + MAPPINGS also make use of a different stellar population synthesis code (Starburst99 by Leitherer et al. 1999).

We ran SUNRISE on the simulations used in this paper, using a SMC dust model and identical initial conditions as adopted for our line-of-sight attenuation calculations. We adopted a birth cloud covering fraction of 0.3, but note that increasing the covering fraction to unity does not significantly alter our results. Populating our model universe using the merger rate function of Section 5, we obtain the model color distribution for the redshift interval $1.5 < z < 3$ shown in Figure 14. The color distribution is plotted separately for the runs with gas fraction $f_{gas} = 0.8$ and $f_{gas} = 0.4$ (see also Section 11.5), and includes both the pre- and the postquasar phase. For reference, we also include panels illustrating the color distribution of massive observed galaxies in the same redshift interval (with masses derived from BC03 and M05 models), and realizations of the model photometry using our line-of-sight attenuation code in combination with BC03 and M05 stellar population synthesis templates. In each of the panels, the color-coding indicates the specific SFR. Typical error bars in the UVJ diagram of observed galaxies are drawn for the quiescent, and blue and red star-forming galaxies separately (their respective regions in UVJ space are outlined by the polygons). Apart from the default SUNRISE photometry, we also present realizations in which one of the aspects of the radiative transfer is switched off. This allows us to disentangle the impact of scattering, birth clouds, and the multiphase breakdown of the ISM.

The default SUNRISE colors lie blueward of our line-of-sight attenuation photometry of the same set of simulations, hence articulating the difficulty of reproducing the colors of observed dusty starbursts (objects in the dark-gray polygon of the observed panels in Figure 14). Whereas—for the colors presented in this diagram—the birth cloud model by Groves et al. (2008) has a negligible impact, we note that accounting for scattering causes a significant part of the blueward shift. Making the assumption that all gas is in the hot phase (i.e., switching off the multiphase breakdown) results in colors that are slightly redder during the star-forming phases than the default SUNRISE photometry, but still significantly bluer than the observed dusty starbursts.

Our analysis highlights the need to understand the details of translating physical quantities to observables (i.e., stellar population synthesis and radiative transfer) in order to effectively constrain models. Moreover, we note that—apart from the freedom in initial gas fraction $f_{gas}$, which for our isolated mergers is set by hand—this issue applies equally, or perhaps more severely, to cosmological simulations, where the spatial resolution is often too limited to apply full radiative transfer.

### 11.4. Dust Distribution

Possibly, the distribution of dust in the simulated galaxies might not reflect reality. A more efficient reddening would be obtained if a foreground screen of obscuring material were present. One possible mechanism that could produce such a configuration on a galactic scale is a large-scale wind. The GADGET-2 code (Springel et al. 2005b) used to run the simulations in principle allows for such a phenomenon, but an investigation of the velocity field of the gas in the simulations is required to check whether such a wind is effectively taking place.

On much smaller scales, below the resolution of the simulations, a more effective reddening might be expected from taking into account that the molecular clouds in which new stars are formed, have a finite lifetime. So far, we ignored the role of birth clouds (except for the comparison with SUNRISE radiative transfer, see Section 11.3), essentially assuming that they are instantaneously dispersed when new stars form. Modeling the attenuation by H II and H I regions around young stars and by the ambient ISM, Charlot & Fall (2000) came up with a simple recipe where the attenuation of light from young stars is increased threefold with respect to the attenuation of the light from old stars, until the birth clouds disperse after $\sim 10^7$ yr. However, applying this recipe as a subgrid model, the integrated SEDs of the simulated galaxies do not always redden over the entire optical-to-NIR wavelength range.

We find that, until the SFR drops shortly after the final coalescence, a threefold extinction toward young stars ($<10$ Myr) reddens the integrated $U - V$ color by 0–0.15 mag. During the early merger phases, we observe a similar trend for the integrated $V - J$ color, with birth clouds causing a reddening of 0–0.1 mag. However, during the nuclear starburst, the trend is reversed and integrated $V - J$ colors bluer by 0–0.15 mag. The reason is that, although young stars are intrinsically bluer, the column densities to the nuclear region where the starburst takes place are so much higher that, even ignoring the attenuation by birth clouds, the young component to the integrated light is redder in $V - J$ than the old component. The balance between reddening and dimming by birth clouds subsequently reddens the already red young component, but downweights its contribution to the integrated light, thus producing a bluer overall color. At later times, the contribution of young stars is negligible, and so are the changes in the integrated colors when applying the simple recipe for birth clouds.

An alternative implementation, in which birth clouds around young stars ($<10$ Myr) have a fixed $A_V = 3$ instead of additional attenuation proportional to the line-of-sight column density through the entire galaxy, suffers from the same downweighting of the young component to the integrated light. Simple birth cloud models of the kind described in this section seem insufficient to produce the colors of dusty starbursts. As described in Section 11.3, the more sophisticated birth cloud model adopted by SUNRISE causes an effective reddening of the $U - V$ and $V - J$ colors, but is also insufficient to account for the colors of observed dusty starbursts.

It is very well possible that the detailed dust distribution, on scales far below the resolution of our simulations, plays a crucial role in determining the galaxy colors. The processes that govern the distribution of dust are highly complex, involving wind escape from massive stars, dust grain formation, and diffusion in the interstellar medium. Unfortunately, we are not able to address those issues with self-consistent numerical modeling in our galactic-scale simulations, at the moment. Although the discussion in Section 11.3 and this subsection does not do justice to the full complexity of the problem, it serves to highlight the uncertainties in the simulated colors.
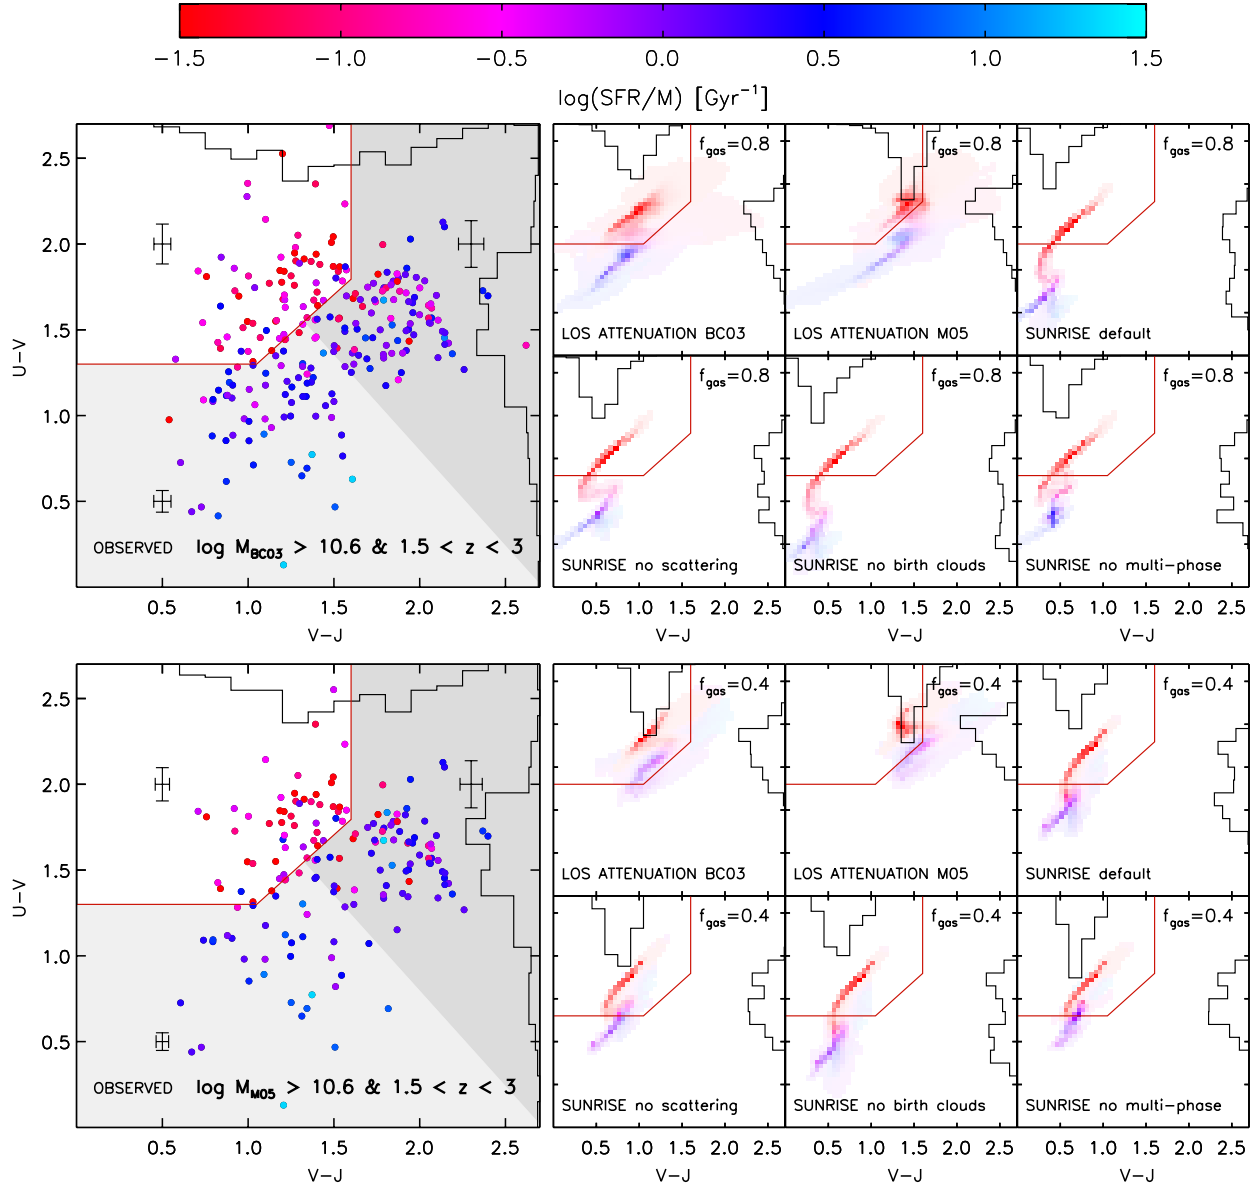

**Figure 14.** Rest-frame *UVJ* color–color diagram of massive galaxies at $1.5 < z < 3$ as observed (big panels), and modeled with a variety of stellar population synthesis codes and radiative transfer methods (small panels). Median error bars are plotted for observed galaxies enclosed by the white, light-gray, and dark-gray polygons. Massive galaxies exhibit a large range of specific SFRs, both in the observations and simulations. The model colors depend on input stellar population synthesis, method of radiative transfer, and initial conditions of the simulations (e.g., initial gas fraction). The model colors of quiescent galaxies are generally consistent with those of their observed counterparts. However, in none of the realizations of the model photometry, the locus of star-forming galaxies extends as far redward (in $U - V$ and particularly $V - J$) as the observations.

(A color version of this figure is available in the online journal.)

### 11.5. Merger Parameters

In addition, the discrepancy in colors might imply that the simulations are not characteristic for the merger activity occurring in the real universe. For example, from the shape of the stellar mass function it can be expected that galaxies at the high-mass end are more likely to merge with galaxies of lower rather than comparable mass (Khochfar & Silk 2006; Peng 2007). Hopkins et al. (2006b) confirmed the robustness of the model for quasar lifetimes and the derived merger rate function against changes in various parameters of the merging galaxies, such as gas fraction, orbital parameters and changes in the mass ratio of the progenitors (considering 1:1, 2:1, 3:1, and 5:1 mass ratios). The conversion from a quasar birthrate to a spheroid birthrate relies on a proper knowledge of the

black hole–bulge mass relation and how it evolves with redshift. This source of uncertainty will be reduced as more stringent observational constraints of the scaling relation at high redshift become available. Considering progenitor mass ratios, Dasyra et al. (2006) find for a population of local ULIRGs that still have two distinct nuclei that the typical mass fraction is 1.5:1, close to equal-mass mergers. In order to refine the model predictions, a detailed study of minor merger simulations is required to determine the minimum mass ratio required to trigger a (low-luminosity) quasar phase.

Finally, all of the simulations used in this work are equal-mass gas-rich mergers ($f_{gas} = 0.8$ at the start of the simulation). In order to study the dependence of our results on the adopted initial gas fraction $f_{gas}$, we repeated our analysis with $f_{gas} = 0.4$ instead of $f_{gas} = 0.8$. Although further gas infall is still not modeled,

this test gives a crude but illustrative characterization of the dependence on the available gas reservoir and may represent differences induced by the gas accretion or evolutionary history. The $f_{gas} = 0.8$ runs represent a scenario in which most of the stars are formed during the merger. In the $f_{gas} = 0.4$ runs on the other hand, the progenitor disks are more mature and a relatively smaller fraction of the final stellar mass is formed in episodes of merger-triggered star formation. The star formation history prior to the start of the simulation is assumed to be constant, and the initial metallicities of gas and stars are set according to a closed box model (see Wuyts et al. 2009 for more details). As a result, the $f_{gas} = 0.4$ runs do not only start with a larger fraction of the baryonic mass in stars, but also with more metal-rich gas ($0.9Z_\odot$ at the start of the simulation) and an initial stellar population having an older mass-weighted age (on the order of 1 Gyr) and larger mass-weighted metallicity ($\sim 0.4Z_\odot$).

In broad terms, our conclusions remain unaltered when lowering the adopted $f_{gas}$ from 0.8 to 0.4. Especially the results regarding the postquasar phase seem robust, since by that time the stellar mass evolution of the low and high gas fraction runs have converged and most of the sensitivity to the initial conditions has been washed out. In other words, the postquasar systems have distinctly lower SFR/$M$ values than the earlier evolutionary stages, their UVJ colors lie in the selection wedge that was designed to select the observed quiescent galaxies, and, as for the $f_{gas} = 0.8$ results, we find that the model prediction for their number and mass density as derived from the observed quasar luminosity function exceeds the observed abundance by a factor of $\sim 2.5$.

For the model predictions of the star-forming population, the following dependencies on $f_{gas}$ are observed. First, in the $f_{gas} = 0.4$ runs more stars already formed prior to the merger-triggered star formation phase. Some systems in the early stages of merging, that in the $f_{gas} = 0.8$ realization had not built up a sufficient amount of mass to enter the sample, will now fall above the mass limit, hence boosting the model prediction and reducing the discrepancy with respect to the abundance of observed massive star-forming galaxies by a factor of $\sim 1.7$. Second, the initial conditions affect the intrinsic photometry of simulated merging galaxies by the increased age and metallicity of the stellar population, and the attenuated photometry is affected also by the smaller amount and larger metal content of the gas. The presence of an old underlying population and relatively smaller build-up of new stars during the merger explains why the tail toward blue $V - J$ and especially blue $U - V$ colors (see Figures 6 and 7) is lacking in the color distribution realized with $f_{gas} = 0.4$. For our default BC03 models, we find the $U - V$ color distribution for the entire (pre- and postquasar) population to range from 1 to 2 with the central 68% interval bracketed by $1.3 < U - V < 1.8$. The $V - J$ distribution ranges from 0.5 to 1.6, with a narrow central 68% interval of $0.9 < V - J < 1.1$. The dependence on population synthesis code and attenuation law is similar as for the higher $f_{gas}$ runs. For example, using M05 models we find a $V - J$ distribution ranging from 1 to 2 (central 68% interval $1.3 < V - J < 1.4$). We conclude that the discrepancy with respect to the optical-to-NIR colors of observed dusty starbursts is not alleviated by adopting a different initial gas fraction. This is also illustrated in Figure 14.

### 11.6. Evolutionary History

Alternatively, it is possible that dusty starburst galaxies are not triggered by mergers, but had a different evolutionary

history. Daddi et al. (2007a) make this claim based on the long star formation timescales of ULIRGs at high redshift, and the relatively tight relation between SFR and stellar mass. We note, however, that our simulations of isolated disk galaxies with initial conditions identical to those of the merger progenitors also fail to produce actively star-forming systems with colors similar to dusty red starbursts. While CO interferometry by Tacconi et al. (2006, 2008) shows key evidence that major merging is taking place in essentially all SMGs, the merger fraction among the general $z \sim 2$ star-forming population may be lower. Spatially resolved kinematic studies by the SINS survey (Förster Schreiber et al. 2006b; Genzel et al. 2006, 2008) and van Starkenburg et al. (2008) show a significant number of rotating disks with high ($\sim 100\,M_\odot\mathrm{yr}^{-1}$) SFR but no evidence for recent or on-going major merging. Applying the method of kinemetry to the SINS sample, Shapiro et al. (2008) find one-third of $z \sim 2$ star-forming galaxies to be undergoing major merging, consistent with our model prediction.

From a theoretical perspective, recent cosmological hydrodynamic simulations have suggested that most of the gas accretion at the high-mass end takes place in cold flows along dark matter filaments, with the streams being $\sim 50\%$ smoothly flowing material, and the other $\sim 50\%$ in clumps of mass ratio $< 10:1$ with respect to the accreting system (Keres et al. 2005; Dekel & Birnboim 2006; Ocvirk et al. 2008; Dekel et al. 2009). Unlike major mergers, such flows could keep the rotating disk configuration observed in many star-forming $z \sim 2$ galaxies intact. Using a semianalytic model with star formation and feedback recipes based on hydrodynamic simulations, Somerville et al. (2008) also find that most of the global star formation occurs in a quiescent mode, rather than in merger-induced starbursts. This could explain why our model prediction for the abundance of merger-triggered star-forming galaxies accounts for only one-third of all observed star-forming galaxies at the high-mass end (see Sections 9.2 and 11.1.2).

We conclude that, while our results are consistent with a scenario where all massive quiescent galaxies at $1.5 < z < 3$ have formed by a merging event that triggered quasar activity, it leaves room for other mechanisms than major mergers contributing significantly to the $z \sim 2$ star-forming population. It would be interesting to scrutinize such alternative scenarios in the same way as presented here.

### 11.7. Mass Loss and Intergalactic Environment

Gas replenishment from mass loss and infall of gas from the intergalactic environment could change the optical depths and thus the reddening factors. The simulations only take into account a small amount of mass loss: 10% of the gas mass converted into stars is instantaneously returned to the interstellar medium, accounting for short-lived stars that die as supernovae (Springel & Hernquist 2003). The total fraction of the mass lost by an aging SSP with Salpeter (1955) IMF amounts to $\sim 30\%$ (BC03) and is even higher ($\sim 50\%$) for more realistic IMFs such as Kroupa (2001) or Chabrier (2003). Furthermore, the simulations do not allow for infall of primordial gas at later times. Consequently, they cannot prove that descendants of galaxies that once showed up in the quasar luminosity function and after the shutdown of star formation reached red colors, will remain quiescent forever. Small amounts of newly accreted gas triggering star formation may be enough to shift a postquasar galaxy outside the quiescent region of color–color space defined by Equation (5), thus dropping their contribution to the observed galaxy population of massive

quiescent red galaxies. Cosmological simulations at sufficient resolution might resolve this problem. At the very least, it would be interesting to test the behavior of simulated merger remnants hosting an SMBH when a small but continuous gas supply is applied.

We note that a rejuvenation of part of the postquasar population would simultaneously improve the agreement with the observations for both the star-forming and the quiescent galaxy abundance.

### 11.8. Cosmic Variance

From the observational side, cosmic variance is the dominant source random of uncertainties for the determination of the number and mass density of massive galaxies. At $z < 2.5$, this is even the case when including the wider area MUSYC survey (Marchesini et al. 2008). This is particularly true for the quiescent population that shows a stronger clustering than the star-forming one (Williams et al. 2009). Surveys over a significantly larger area than FIRES and GOODS-South, but probing similar depths at optical-to-MIR wavelengths, are required to better constrain the fraction of massive quiescent galaxies that postquasar galaxies can account for. The ultraVISTA survey by Dunlop, Franx, Fynbo, and LeFèvre will provide NIR imaging over half of the 2 deg$^2$ COSMOS field to an unprecedented depth. In combination with very deep IRAC imaging during the warm *Spitzer* mission, such multiwavelength surveys will allow us to simultaneously probe further down the mass function of quiescent galaxies, and reduce the effect of cosmic variance.

### 12. SUMMARY

We confronted the model by Hopkins et al. (2006b) with observations of massive galaxies at $1.5 < z < 3$. The model translates the observed quasar luminosity function into the abundance of massive merging galaxies and merger remnants. We derived the synthetic photometry for these systems from a set of binary merger SPH simulations by Robertson et al. (2006a, 2006b) and T. J. Cox, with a range of masses, and including stellar and AGN feedback. We extracted mass-limited samples of $1.5 < z < 3$ galaxies with $M > 4 \times 10^{10} M_\odot$ and $M > 10^{11} M_\odot$ from the FIRES+FIREWORKS and FIRES+FIREWORKS+MUSYC surveys, respectively. We tested the model by comparing the predicted number and mass densities, the $U - V$ and $V - J$ color distributions, and SFR/$M$ versus mass distribution with our observations of massive galaxies at $1.5 < z < 3$.

We find that the overall number density of galaxies with $M > 4 \times 10^{10} M_\odot$ in the FIRES and GOODS-South fields ($n = 4.0^{+1.3}_{-1.3} \times 10^{-4}$ Mpc$^{-3}$ at $z \sim 1.9$ and $n = 3.3^{+1.1}_{-1.2} \times 10^{-4}$ Mpc$^{-3}$ at $z \sim 2.6$) is consistent within the uncertainties with the model prediction ($n = 4.8$–$5.5 \times 10^{-4}$ Mpc$^{-3}$ at $z \sim 1.9$ and $n = 1.9$–$2.2 \times 10^{-4}$ Mpc$^{-3}$ at $z \sim 2.6$). Likewise, the results obtained for the mass density are consistent: $\rho_* = 3.8^{+1.3}_{-1.2} \times 10^7 M_\odot$ Mpc$^{-3}$ at $z \sim 1.9$ and $\rho_* = 2.8^{+0.9}_{-0.9} \times 10^7 M_\odot$ Mpc$^{-3}$ at $z \sim 2.6$ for the observations and $\rho_* = 5.4$–$6.0 \times 10^7 M_\odot$ Mpc$^{-3}$ at $z \sim 1.9$ and $\rho_* = 1.9$–$2.2 \times 10^7 M_\odot$ Mpc$^{-3}$ at $z \sim 2.6$.

Separating massive galaxies by type, we find that the model photometry of the postquasar population coincides with the region of $U - V$ versus $V - J$ color–color space that was defined by I. Labbé et al. (2009, in preparation) to select quiescent red galaxies. The modeled number and mass densities of massive ($M > 4 \times 10^{10} M_\odot$) quiescent galaxies is consistent with the observations at $z \sim 2.6$, but somewhat larger (2–3 times) than

observed at $z \sim 1.9$. The results based on the UVJ diagnostic diagram and on a MIPS-based SFR/$M$ threshold are consistent.

We added the MUSYC survey to our sample, increasing the area by a factor of 3.6, but by the shallower depth restricting our analysis to $M > 10^{11} M_\odot$ galaxies. From this sample, we derive qualitatively similar results.

Although less constrained, the predicted abundances of galaxies with merger-triggered star formation (according to their *UVJ* colors or SFR/$M > 1/t_{\rm Hubble}$ can also account for a significant fraction of the observed actively star-forming galaxies (one-third when using masses based on BC03 templates and taking into account biases in SED modeling). However, the predicted color distribution of star-forming galaxies does not match the observations. In particular, the colors of red ($V - J > 1.8$) dusty starburst galaxies are not reproduced. We suggest a number of explanations for the lack of dusty red starburst galaxies in the model predictions. Possible reasons are an incomplete simulation of the observing procedure, differences in stellar population properties or merger characteristics between the observed and simulated galaxies, a different history for dusty starbursts than a merger-triggered scenario, infall of additional gas (and dust) from the intergalactic environment or mass loss, and a different distribution of the dust, e.g., caused by the presence of large-scale outflows or birth clouds around young stars.

Finally, we find hints of a pair excess at small angular scales, further strengthening the hypothesis that mergers play a key role in galaxy evolution.

We conclude that the star formation in remnants of merger simulations is quenched abruptly, leading to colors that correspond well to those of observed massive galaxies with a quiescent stellar population. Using a merger rate derived from the observed quasar luminosity function, we obtain number and mass densities of the quiescent population at $1.5 < z < 3$ that are consistent within a factor of 2–3 with the observations. Possibly, the overprediction at $z \sim 1.9$ suggests the need to include gas infall as refinement to the model. The predicted abundance of merger-triggered star-forming systems accounts for 30%–50% of the observed star-forming population, leaving ample room for other star formation mechanisms than major merging. The most serious challenge to the model is posed by the color distribution of star-forming galaxies, which is not well reproduced. The detailed dust distribution, on a galaxy-wide scale and/or scales far below the resolution of the simulation, may well cause this problem. With this work, we hope to encourage further investigations focusing on the translation of simulated physical quantities to observables.
