## ABSTRACT

We consider local, stratified, numerical models of isothermal accretion disks. The novel feature of our treatment is that radial extent $L_x$ and azimuthal extent $L_y$ satisfy $H \ll L_x, L_y \ll R$, where $H$ is the scale height and $R$ is the local radius. This enables us to probe *mesoscale* structure in stratified thin disks. We evolve the model at several resolutions, sizes, and initial magnetic field strengths. Consistent with earlier work, we find that the saturated, turbulent state consists of a weakly magnetized disk midplane coupled to a strongly magnetized corona, with a transition at $|z| \sim 2H$. The saturated $\alpha \simeq 0.01$–$0.02$. A two-point correlation function analysis reveals that the central $4H$ of the disk is dominated by small-scale turbulence that is statistically similar to unstratified disk models, while the coronal magnetic fields are correlated on scales $\sim 10H$. Nevertheless angular momentum transport through the corona is small. A study of magnetic field loops in the corona reveals few open field lines and predominantly toroidal loops with a characteristic distance between footpoints that is $\sim H$. Finally, we find quasi-periodic oscillations with characteristic timescale $\sim 30\,\Omega^{-1}$ in the magnetic field energy density. These oscillations are correlated with oscillations in the mean azimuthal field; we present a phenomenological, alpha-dynamo model that captures most aspects of the oscillations.

## 1. INTRODUCTION

The physics of angular momentum transport is at the core of accretion disk studies. Classical viscous thin disk theories (Shakura & Sunyaev 1973; Lynden-Bell & Pringle 1974; Novikov & Thorne 1973) assume the existence of a local turbulent viscous stress, thus provide a simple local parameterization, i.e., "anomalous viscosity" $\alpha$, for disk momentum transport and dissipation. Since the early 1990s, the magnetorotational instability (MRI; Balbus & Hawley 1991) has been regarded as the best candidate to drive accretion disk turbulence, although gravitational torque or magnetic winds of a Blandford & Payne (1982) type can also enhance angular momentum transport.

Classical thin disk theories are vertically integrated and azimuthally averaged, and are therefore essentially one dimensional. Currently, disk vertical structure can only be obtained from numerical simulations where turbulence is established from first-principle instabilities such as the MRI. Global disk simulations are just starting to investigate thin disks (Reynolds & Fabian 2008; Shafee et al. 2008; Noble et al. 2009), but they are computationally expensive and not yet able to fully resolve turbulent structures in the disk. Shearing box simulations, on the other hand, can concentrate resolution on disk dynamics at scales of order the disk scale height $H \equiv c_s/\Omega$, and therefore are more suitable to study accretion flows in detail. Past studies of shearing box simulations with vertical gravity (e.g., Brandenburg et al. 1995; Stone et al. 1996; Miller & Stone 2000; Hirose et al. 2006; Blaes et al. 2007; Suzuki & Inutsuka 2009) have revealed a rich set of structures and dynamics in stratified disks. However, all of these stratified shearing box simulations were done with a box of limited radial extent $L_x \sim H$, therefore they were not able to explore any structure on scales larger than $H$. Recently, Davis et al. (2010) have studied a stratified shearing box of radial extent $L_x = 4H$, and Johansen et al. (2009)

have adopted models of box size up to $L_x \sim 10H$ in their zonal flow studies. However, both of these studies are limited to the small vertical extent ($\sim \pm 2H$) and physically unrealistic periodic vertical boundary conditions. In this paper, we study the dynamics and structure in isothermal stratified disks using large shearing box with domain sizes $L_x \geqslant 10H$ in all directions.

We still do not know whether a magnetized turbulent disk is well modeled as a steady-state, locally dissipated disk model. It is possible, for example, that structures (gas and/or fields) develop at a scale large compared with $H$ and that these structures could be associated with nonlocal energy or angular momentum transport. Large-scale structures might also develop in the magnetic field in the form of a dynamo. The disk might also be secularly unstable (see the overview by Piran 1978), which could cause the disk to break up into rings. It is well known that a Navier–Stokes viscosity model for disk turbulence leads, for some opacity regimes, to both viscous (Lightman & Eardley 1974) and thermal (Piran 1978) instability, although it is now believed that thermal instability can be removed by delays imposed through finite relaxation time effects in MRI-driven turbulence (Hirose et al. 2009).

From an observational point of view, the level of fluctuations (inhomogeneity) at different locations in disks and how these different locations communicate with each other have important consequences for disk spectra modeling (Davis et al. 2005; Blaes et al. 2006). In these models, observational diagnostics require integrating over the disk surface, so radially extended structure in the disk model may change the disk spectrum. Our disk model is isothermal (we do not solve an energy equation) and is therefore not capable of being used to investigate dissipation and radiation. It is possible that larger fluctuations would appear in physically richer models where thermodynamics and radiative effects are taken into account (e.g., Turner et al. 2003; Turner 2004). It would then be interesting in the future for spectral modelers to consider disk models with larger radial domains.

A shearing box larger than $H$ is also essential to catch the field structure and dynamics in the accretion disk magnetic coronae (Tout & Pringle 1996; also see a discussion in Uzdensky & Goodman 2008), where the field has a characteristic curvature $l \sim v_a / \Omega \gtrsim H$, and $v_a$ is the characteristic Alfvén speed in the region.

Recently, it has also been pointed out that a large box size may be important to study the saturation properties of the MRI-driven turbulence, either on the ground of resolving parasitic modes (Pessah & Goodman 2009) or in a phenomenological model of an MRI-driven dynamo (Vishniac 2009). Saturation mechanisms in a stratified disk may be fundamentally different from those in unstratified disks. Recent numerical experiments on unstratified disks suggest that (1) with a zero-net flux, the saturation decreases with resolution (Fromang & Papaloizou 2007), and is dependent on the microscopic Prandtl number $\mathrm{Pr}_M$ in the disk, at least at low Reynolds number (Fromang et al. 2007; Simon & Hawley 2009); (2) with a net (toroidal or vertical) flux, the saturation increases with resolution (Hawley et al. 1995; Guan et al. 2009), and is also dependent on $\mathrm{Pr}_M$, at least at low Reynolds number (Lesur & Longaretti 2007; Simon & Hawley 2009; Longaretti & Lesur 2010). Stratified disk models, which are closer to real disks, may well maintain a net (most likely, toroidal; see a discussion in Guan & Gammie 2009) field in the disk region because of the magnetic buoyancy induced by stratification. Therefore, we expect saturation in stratified disk models to differ from that of unstratified models.

It is worth enumerating the assumptions we adopt in this work: (1) we use an isothermal equation of state (EOS) in our models, (2) the vertical support comes from the gas and magnetic pressure rather than the radiation pressure, (3) there is no explicit viscosity or resistivity, (4) our initial conditions consist of a uniform toroidal field in a region near the disk midplane, and (5) we use outflow boundary conditions for the vertical boundaries.

The paper is organized as follows. In Section 2, we give a description of the local model and summarize our numerical algorithm. In Section 3, we present a fiducial model and analyze its structure in the saturated state. In Section 4, we describe how this structure depends on model parameters. In Section 5, we give a report on quasi-periodic oscillations (QPOs; "butterfly diagrams") and present a phenomenological model to describe them that is based on a mean field dynamo model; Section 5 contains a summary of our results.

## 2. LOCAL MODEL AND NUMERICAL METHODS

The local model for disks can be obtained by expanding the equations of motion around a circular-orbiting coordinate origin, with $(r, \phi, z) = (r_o, \Omega_o t + \phi_o, 0)$ in cylindrical coordinates, assuming that the peculiar velocities are comparable to the sound speed and that the sound speed is small compared with the orbital velocity. The local Cartesian coordinates are then obtained from cylindrical coordinates via $(x, y, z) = (r - r_o, r_o[\phi - \Omega_o t - \phi_o], z)$. In this work, we assume the disk sits in a Keplerian $(1/r)$ potential. We also use an isothermal ($p = c_s^2 \rho$, where $c_s$ is constant) EOS.

For an ideal MHD disk, the equation of motion in the local model is

$$\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{v} \cdot \boldsymbol{\nabla} \boldsymbol{v} + c_s^2 \frac{\boldsymbol{\nabla} \rho}{\rho} + \frac{\boldsymbol{\nabla} B^2}{8\pi\rho} - \frac{(\boldsymbol{B} \cdot \boldsymbol{\nabla})\boldsymbol{B}}{4\pi\rho}$$
$$+ 2\boldsymbol{\Omega} \times \boldsymbol{v} - 3\Omega^2 x\,\hat{\boldsymbol{x}} + \Omega^2 z\,\hat{\boldsymbol{z}} = 0. \quad (1)$$

From left to right, the last three terms in Equation (1) represent the Coriolis force, tidal forces, and vertical gravitational acceleration in the local frame, respectively. The orbital velocity in the local model is

$$\boldsymbol{v}_{\mathrm{orb}} = -\frac{3}{2}\,\Omega x\,\hat{\boldsymbol{y}}. \quad (2)$$

This velocity, along with a vertical density profile $\rho(z) = \rho_0 \exp[-\Omega^2 z^2 / (2c_s^2)]$ and zero magnetic field, is a steady-state solution to Equation (1). $\rho_0$ is the midplane density. In this work, we nondimensionalize the local model by choosing $\rho_0 = 1$, $\Omega = 1$, and $c_s = 1$; the usual disk scale height $H$ is therefore $H \equiv c_s / \Omega = 1$. The initial surface density is therefore $\int \rho\, dz = \sqrt{2\pi}\,\rho_o$.

The local model is realized numerically using the "shearing box" boundary conditions (e.g., Hawley et al. 1995), which isolates a rectangular region in the disk. The azimuthal ($y$) boundaries are periodic; the radial ($x$) boundaries are "shearing periodic"; they connect the radial boundaries in a time-dependent way that enforces the mean shear. The vertical ($z$) boundaries use a form of outflow boundary conditions: all variables in ghost zones (including the $z$ velocity and momentum on vertical boundaries because of the staggered mesh) are copied from the last active zone in the computational domain, with the additional constraint that no inflow is allowed. For stratified disk models, the outflow boundary condition is better motivated than periodic boundary conditions, although it is more difficult to implement.

What constraint do these boundary conditions place on the field evolution? Integrating the induction equation over the computational domain yields, after application of Stokes theorem,

$$L_x L_y L_z \partial_t \langle B_x \rangle \equiv \partial_t \int d^3 x\, B_x = \int dx \int d[s] \cdot (\boldsymbol{v} \times \boldsymbol{B}), \quad (3)$$

where the second integral is taken on a circuit round the box boundaries at fixed $x$. It is evident that the electromotive force (EMF) integrated over a line on the top boundary will not cancel that on the bottom boundary for outflow boundary conditions, and so $\langle B_x \rangle$ is not conserved. A similar argument implies that $\langle B_y \rangle$ is not conserved either. $\partial_t \langle B_z \rangle$ is proportional to a line integral around the box at constant $z$, where the quasi-periodic radial and periodic azimuthal boundary conditions do cause cancellation, so $\langle B_z \rangle$ is constant (numerically: constant to within accumulated roundoff error).

In the preceding paragraph, we adopted the notation $\langle\ \rangle$ for a volume average:

$$\langle f \rangle \equiv \frac{1}{V} \int_V dx\, dy\, dz\, f. \quad (4)$$

We will also use

$$[f] \equiv \frac{1}{L_x L_y} \int dx\, dy\, f \quad (5)$$

for a plane average and

$$\bar{f} \equiv \frac{1}{T} \int_T dt\, f \quad (6)$$

for a time average.

Our models are evolved using ZEUS (Stone & Norman 1992) with "orbital advection" (see Masset 2000; Gammie 2001; Johnson & Gammie 2005, aka FARGO) for the magnetic field

(Johnson et al. 2008; Fromang & Stone 2009). ZEUS is an operator-split, finite-difference scheme on a staggered mesh that uses a Von Neumann–Richtmyer artificial viscosity to capture shocks (this is a nonlinear bulk viscosity that does not produce significant angular momentum transport in our models), and the Method of Characteristics-Constrained Transport (MOC-CT) scheme to evolve the magnetic field and preserve the $\nabla \cdot \boldsymbol{B} = 0$ constraint to machine precision. The orbital advection is implemented on top of ZEUS. It decomposes the velocity field into a mean shear part with orbital velocity $\boldsymbol{v}_{\mathrm{orb}} = -q\Omega x[\hat{y}]$ and a fluctuating part $\delta\boldsymbol{v}$; $\boldsymbol{v} = \delta\boldsymbol{v} + \boldsymbol{v}_{\mathrm{orb}}$. Advection for the mean flow can be done using interpolation (which is always stable), so that the Courant limit on the time step depends only on $\delta\boldsymbol{v}$ and not on $\boldsymbol{v}_{\mathrm{orb}}$. Shearing boxes with $L_x \gtrsim H$, where the shear flow is supersonic, can then be evolved more accurately, and with a larger time step.

We have also implemented an additional procedure to make the numerical diffusion more nearly translation invariant in the plane of the disk. As discussed in Guan & Gammie (2009), the entire box is shifted by a few grid points in the radial direction at $t = 2nL_y/(3\Omega L_x)$, $n = 1, 2, 3, \ldots$; at these instants the box is exactly periodic. After the shift we execute a divergence cleaning procedure to remove the monopoles that are created by joining the radial boundaries together in the middle of the computational domain. This procedure carries little computational cost.

The time step in large stratified disk simulations is limited through the Courant condition by the Alfvén speed $v_A = B/\sqrt{4\pi\rho}$ at large $|z|/H$, where the density is orders of magnitude smaller than that at $z = 0$. To prevent the simulation from being brought to a halt by low density zones (and to avoid other numerical artifacts associated with small $\rho$), we impose a density floor $\rho_{\mathrm{min}} = 10^{-5}\rho_0$. This density floor is $\sim 1$–$2$ orders of magnitude smaller than the averaged minimum density in the saturated state. We have tested a smaller density floor $\rho_{\mathrm{min}} = 10^{-7}\rho_0$ and found the choice of the density floor does not affect our results.

## 3. LARGE STRATIFIED DISK SIMULATIONS

### 3.1. Fiducial Model

All models start from a hydrodynamical equilibrium, with $\rho(z) = \rho_0 \exp(-z^2/[2H^2])$. We introduce a uniform toroidal field $\boldsymbol{B}_0 = B_0\hat{y}$ at $|z| \leqslant 2H$; $B_0$ is chosen so that at the disk midplane the initial plasma parameter $\beta_0 \equiv 8\pi P_0/B_0^2 = 25$ (the sharp vertical variation in $B_y$ at $|z| = 2H$ makes the disk initially unstable to magnetic Rayleigh–Taylor instability, but this structure is quickly wiped out by MRI-driven turbulence). Each component of the velocity is perturbed in each zone, with $\delta v_i$ uniformly distributed in $[-0.01, 0.01]c_s$. The models are evolved long enough ($\geqslant 150$ orbits $\sim 900\,\Omega^{-1}$) to reach a saturated, i.e., statistically steady, state.

Our fiducial model has a domain size of $(L_x, L_y, L_z) = (16, 20, 10)H$ and resolution $384 \times 256 \times 128$. This corresponds to a physical resolution of $(24, 12.8, 12.8)$ zones per scale height. Snapshots of $\rho$ and $E_B \equiv B^2/8\pi$ at slices with constant $x$, $y$, and $z$ in the saturated state are shown in Figure 1.

Turbulence is confined to the region $|z| \leqslant 2H$. Within this region magnetic field fluctuations are contained on a scale $l \ll H$, with a structure in the shape of narrow filaments that are extended by the azimuthal shear. This turbulent field structure resembles that observed in unstratified disk simulations (Guan & Gammie 2009). Density fluctuations on a scale $\sim H$ due to

sound waves are also evident in the $x$–$z$ plane density snapshots. At $|z| > 2H$, the MRI is suppressed. $E_B$ decreases sharply, but not as rapidly as $\rho$.

The disk vertical structure is shown in Figure 2, which shows $\overline{[\rho]}$, $\overline{[E_B]}$, $\overline{[\beta]}$, Maxwell (magnetic) stress $\overline{[M_{xy}]} \equiv \overline{[-B_x B_y]}/4\pi$, and Reynolds stress $\overline{[R_{xy}]} = \overline{[\rho v_x \delta v_y]}$. These profiles are obtained from a time average over the last $100\pi/\Omega$. The most striking feature in these profiles is the "turbulent disk surface" at $|z| \sim 2H$ defined by $\overline{[E_B]}(z)$ and $\overline{[M_{xy}]}(z)$. Inside this surface both are independent of $z$; outside both exhibit an approximately exponential dependence on $z$. As illustrated in the vertical profile of $\beta$, as $|z|$ increases, magnetic energy density drops slower than density; above $|z| \sim 2.5H$ $\beta$ drops below unity. Therefore, the region $|z| > 2H$ is magnetically dominated and this leads to the suppression of the MRI. From now on we will simply refer to the magnetically dominated upper region with $\beta < 1$ as "corona" and the turbulent $|z| \leqslant 2H$ region as "disk."

Fits to the disk structure give

$$\overline{[\rho]}(z) \simeq \begin{cases} 0.93\rho_o \exp\left(-\frac{z^2}{2H}\right), & \text{if } |z| \leqslant 2.55H; \\ 0.036\rho_o \exp\left(-\frac{|z|-2.6H}{0.44H}\right), & \text{otherwise,} \end{cases} \tag{7}$$

and

$$\overline{[E_B]}(z) \simeq \begin{cases} 0.012\rho_0 c_s^2, & \text{if } |z| \leqslant 2.55H; \\ 0.012 \exp\left(-\frac{|z|-2.6H}{0.64H}\right)\rho_0 c_s^2, & \text{otherwise.} \end{cases} \tag{8}$$

In the saturated state, $\overline{[\rho]}(z)$ is different from the initial density profile $\rho_0 \exp[-z^2/(2H^2)]$ due to the magnetic buoyancy effects and mass loss through the $z$ boundaries. Inside the disk, a nearly Gaussian density profile indicates that this region is still mainly supported by gas pressure.

How can we understand the vertical magnetic structure of the disk? A uniformly magnetized atmosphere is subject to interchange and Parker-type modes (Newcomb 1961; Parker 1966). The more dangerous of these are Parker-type modes, whose stability condition is

$$-\frac{d\rho}{dz} > \frac{\rho^2 g}{\gamma P_{\mathrm{gas}}}, \tag{9}$$

where $P_{\mathrm{gas}}$ is the gas pressure, $g = \Omega^2 z$ is the gravitational acceleration, and $\gamma$ is the adiabatic index (here $\gamma = 1$; Newcomb 1961). For a disk in hydrostatic equilibrium,

$$-\frac{d(P_{\mathrm{gas}} + P_{\mathrm{mag}})}{dz} = \rho g. \tag{10}$$

Together these conditions imply

$$\frac{dP_{\mathrm{mag}}}{dz} = \frac{dE_B}{dz} = 0. \tag{11}$$

Marginally stable stratification therefore corresponds to constant $\overline{[E_B]}$, as is found at $|z| < 2H$. This suggests that (1) magnetic buoyancy is driving the disk toward a marginally stable state and (2) magnetic buoyancy is crucial in controlling the vertical magnetic structure in the bulk of the disk. If this is correct, it follows that $E_B(z)$ in the disk could be different in nonisothermal models. In particular, marginal stability requires

$$\frac{1}{8\pi}\frac{d[B^2]}{dz} = \gamma P_{\mathrm{gas}}\left(\frac{1}{\gamma}\frac{d\ln P_{\mathrm{gas}}}{dz} - \frac{d\ln\rho}{dz}\right). \tag{12}$$
**Figure 1.** Snapshots of density and magnetic energy density in the fiducial model, taken at $t = 100$ orbits. Left: density $\rho$; right: magnetic energy density $E_B$; top: image at $y = 0$ plane; middle: image at $x = 0$ plane; bottom: image at $z = 0$ plane.
(A color version of this figure is available in the online journal.)

Thus an isentropic disk has $dB^2/dz = 0$, while a stably stratified, nonradiative disk (in the Schwarzschild sense) can support $dB^2/dz < 0$. In a radiative disk, the instability criterion is modified (disks heated by internal dissipation of turbulence rather than external irradiation tend to have strong radiative diffusion or Peclet numbers of order $\alpha^{-1} \sim 50$), because radial radiative diffusion tends to wipe out temperature perturbations for the most unstable modes with high radial wavenumbers.

Figure 3 shows the evolution of magnetic energy density in the disk $\langle E_{B,\mathrm{d}} \rangle$, magnetic energy density in the corona $\langle E_{B,\mathrm{c}} \rangle$, and $\langle \alpha \rangle$:

$$\langle \alpha \rangle \equiv \frac{\int W_{xy} d^3 x}{\int \rho c_s^2 d^3 x}, \qquad (13)$$

where $W_{xy} \equiv R_{xy} + M_{xy}$ is the total shear stress. Averaging the last 50 orbits, we found that $\overline{\langle \alpha \rangle} \sim 0.013$, $\overline{\langle E_{B,\mathrm{d}} \rangle}/\rho_0 c_s^2 \sim 0.012$, and $\overline{\langle E_{B,\mathrm{c}} \rangle}/\rho_0 c_s^2 \sim 0.0043$.

### 3.2. Two-point Correlation Function

One question motivating this study was whether thin disks exhibit mesoscale structure, i.e., structure on scales that are $\gg H$ but $\ll R$. As is evident in Figure 1, the characteristic scale of the magnetic energy density varies with $|z|$. Near $|z| = 0$, turbulent structure resembles that observed in unstratified disk models: the field is confined in small structures with scale $l \ll H$. Away from $|z| = 0$, $l$ increases, reaching $\sim H$ at $|z| \sim 2.5H$.

The two-point correlation function $\xi$ provides a quantitative measure of disk structure:

$$\xi_B(z) \equiv [\delta \boldsymbol{B}(x, y; z) \cdot \delta \boldsymbol{B}(x + \Delta x, y + \Delta y; z)]. \qquad (14)$$

Here $\delta \boldsymbol{B} \equiv \boldsymbol{B} - [\boldsymbol{B}]$; for a detailed discussion of $\xi$ and the corresponding correlation lengths $\lambda_i$ see Guan et al. (2009). Figure 4 shows $\xi_B(z)$ in the $(\Delta x, \Delta y)$ plane at $z = 0$, $z = 2.5H$, and $z = 4.5H$. In these plots, we have averaged eight
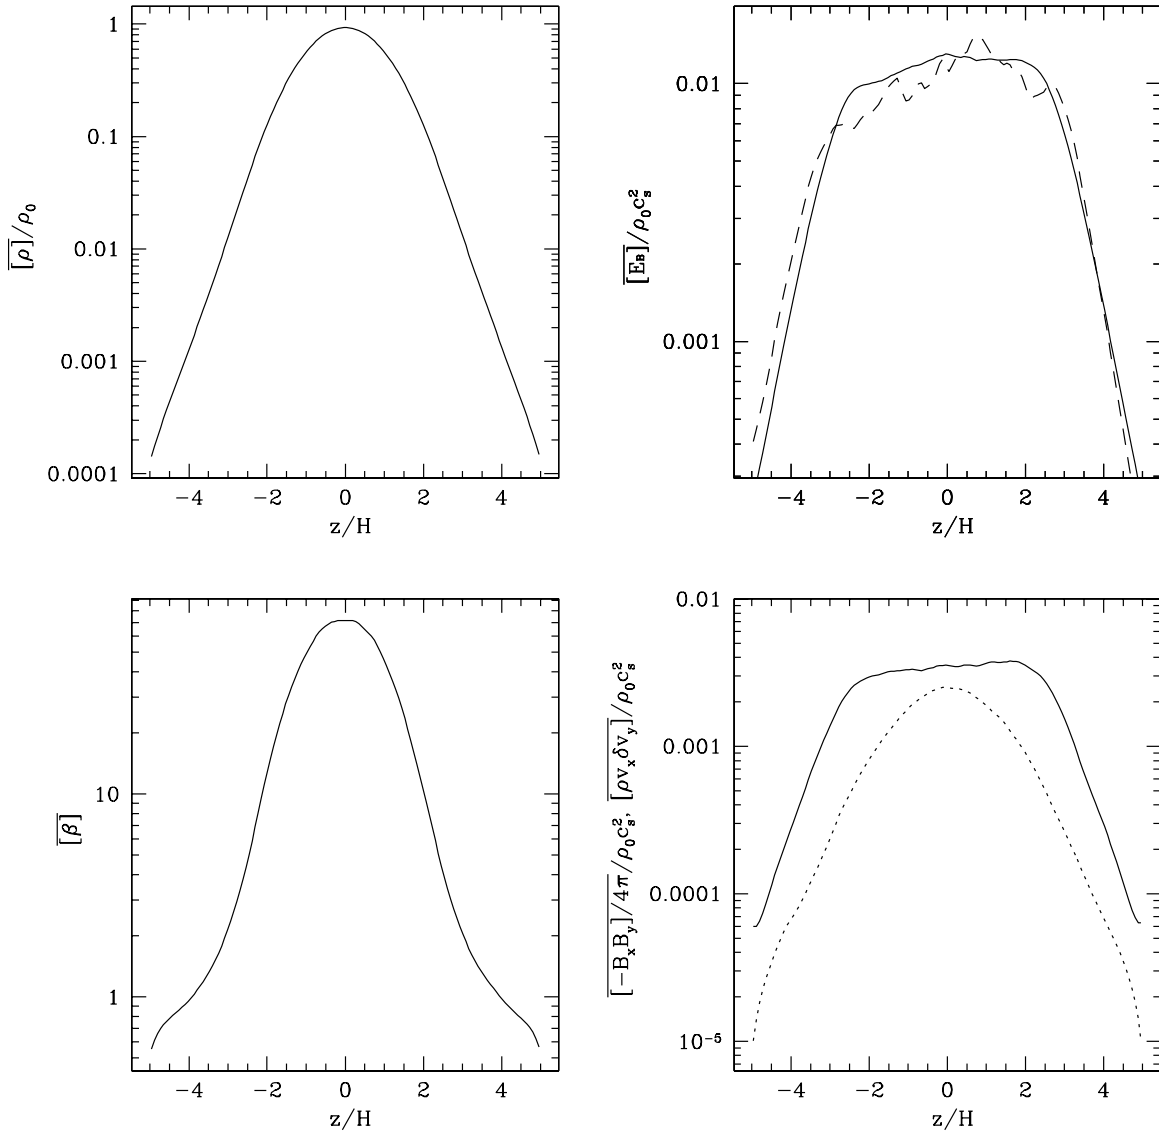

**Figure 2.** Vertical profiles of several $x-y$ plane-averaged quantities in the fiducial model. Upper left: density; upper right: magnetic energy density; lower left: plasma $\beta$; lower right: $xy$ component of Maxwell stress $M_{xy} = -B_x B_y/4\pi$ (solid lines) and Reynolds stress $R_{xy} = \rho v_x \delta v_y$ (dotted lines). All quantities in solid and dotted lines are averaged from the last 50 orbits. To illustrate the time average effect, we also plot $[E_B](z)$ at $t = 900\,\Omega^{-1}$ (dashed lines) in the upper right panel. The slight asymmetry of $\overline{[E_B]}(z)$ and $\overline{[M_{xy}]}(z)$ in the $|z| \leqslant 2H$ region is probably due to our choice of orbits interval for time average.

neighboring vertical zones to increase the signal-to-noise ratio. At the disk midplane, the correlation function has a narrow elliptical core of width $\lambda <$ a few $H$. As $|z|$ increase to $2.5H$ the core becomes larger, especially in the radiation direction, and low-amplitude features develop on scales of $\sim 10H$. These low-amplitude, mesoscale features are new and are not seen in unstratified disk models.

### 3.3. Coronal Loop Structure

Our disk models contain a "corona," where $\beta < 1$. It is not clear how accurately, or inaccurately, our code models this region because it contains no explicit model for reconnection (which is the case for any convincing model currently available; see Uzdensky & Goodman 2008 for a discussion of the difficulties of simulating force-free coronae). Still, it is interesting to characterize the field structure in existing simulations before asking how they might be changed by more sophisticated reconnection models.

How can we understand coronal magnetic field structure? Most of the coronal field is anchored in the disk, so we begin by sampling field lines that rise through the surface $z = 2.5H$ at a single instant. Using bilinear interpolation for the field, we trace field lines initiated from every cell on the $z = 2.5H$ surface, until they either (1) come back to the $z = 2.5H$ surface, or (2) leave the upper $z$ surface, or (3) exceed maximum integration step $10^5$ indicating the formation of a closed loop. A snapshot of these field lines is shown in Figure 5. Two features of the coronal field are obvious just from visual inspection: many of the field lines return to the disk after only a short sojourn in the corona, and the loops tend to have greater azimuthal than radial extent.

A more quantitative approach is to calculate a coronal loop distribution function, as in the phenomenological model of (Uzdensky & Goodman 2008, hereafter UG). The field lines should then be sampled according to the flux through each zone surface $d\Phi_i = B_{z,i}dxdy$. We also average over the last 50 orbits to improve the loop statistics. We find that $\sim 96\%$ of the field lines passing through the $z = 2.5H$ surface return to the same surface, $\sim 4\%$ of field lines are open in the sense that they
**Figure 3.** Evolution of $\langle\alpha\rangle$ (solid lines), $\langle E_{B,d}\rangle/\rho_0 c_s^2$ at $|z| \leqslant 2H$ (dotted lines), and $\langle E_{B,c}\rangle/\rho_0 c_s^2$ at $|z| > 2H$ (dashed lines) in the fiducial model. Saturation $\overline{\langle\alpha\rangle} \sim 0.013$ when averaged over the last 50 orbits.

**Figure 4.** Contour plots of two-dimensional two-point correlation function $\xi_B(z)$ for $\delta\boldsymbol{B}$. Plotted are $\xi_B(z)/(4\pi\rho_0 c_s^2)$ in the $(\Delta x, \Delta y)$ plane at three different vertical heights in the fiducial model. Left: midplane; middle: $z = 2.5H$; right: $z = 4.5H$. The contours run linearly from $-0.058$ to $0.229$ for 20 levels; solid lines: $\xi_B \geqslant 0$; dashed lines: $\xi_B < 0$; the heavy line is the 0 contour.

**Figure 5.** Magnetic field lines originating from the plane $z = 2.5H$ in the fiducial model at $t = 600\,\Omega^{-1}$. The lines are evenly sampled spatially from the $x$–$y$ plane. Both the line width and the color denote the flux carried by each line at the footpoint, normalized by the total flux from the $z = 2.5H$ plane. The majority of the field lines return to $z = 2.5H$, forming closed loops.

(A color version of this figure is available in the online journal.)

**Figure 6.** Loop angle distribution functions in the fiducial model: $\theta$ denotes the angle between the foot separation vector and the $y$-axis. Loops are stretched in the azimuthal direction due to the shear.

escape through the upper boundary of the box, and only $\sim 0.1\%$ of the field lines form closed loops inside the corona. We have also found that the small fraction of the open field lines is quite stable during the saturated state, ranging from $\sim 2\%$–$5\%$ at instantaneous state; therefore it appears that the corona field structure has reached a statistical steady state.

We then use three variables to describe the geometry of close field lines (field loops) that return to the $z = 2.5H$ surface: the loop footpoint separation $\Delta x$ in the $x$–$y$ plane, the loop maximum height $\Delta z_{\max}$, and the loop orientation angle $\theta_{\mathrm{foot}} \equiv$ the angle between the foot separation vector and the $y$-axis. We calculate the distribution functions $d\Phi/d\Delta x$, $d\Phi/d\Delta y$, $d\Phi/d\Delta z_{\max}$, and $d\Phi/d\theta_{\mathrm{foot}}$ by following the trajectory of every

field line that emerges at the center of each zone surface $i$, then weighting the result by the flux $d\Phi_i$. The final distribution function is normalized by $|\Phi|$, the total absolute flux through the $z = 2.5H$ plane.

Figures 6 and 7 show $d\Phi/d\Delta x$, $d\Phi/d\Delta y$, $d\Phi/d\Delta z_{\max}$, and $d\Phi/d\theta_{\mathrm{foot}}$, averaged over the last 50 orbits. From $d\Phi/d\theta_{\mathrm{foot}}$ (Figure 6), it is evident that most of the field loops are orientated in the azimuthal direction with $\theta \leqslant$ a few degrees. This suggests that shear plays a significant role in determining the coronal field structures. Most loops also have maximum height $\Delta z_{\max} \leqslant H$ (see $d\Phi/d\theta_{\mathrm{foot}}$ in Figure 7).

If there is no reconnection at all then magnetic energy injection from the underlying turbulent disk might cause the loop to grow in an unlimited way. This is not the case here: although we do not include dissipation explicitly, numerical reconnection due to truncation errors is present in our numerical scheme, as
**Figure 7.** Loop distribution functions in the fiducial model. Left panel: footpoint separation distribution. The left curve is for $\Delta x$ and the right curve is for $\Delta y$. The distribution for $\Delta L = (\Delta x^2 + \Delta y^2)^{1/2}$ almost overlaps with the $\Delta y$ curve. The heavy line indicates a $k = -5/4$ slope. Right panel: loop height distribution.

in all finite-difference MHD schemes. It is difficult, however, to quantify the numerical reconnection rate in our model directly. We therefore try to compare our numerical loop distributions to the predictions of the UG model.

We fit a power law to $d\Phi/d\Delta x$ and $d\Phi/d\Delta y$,

$$\frac{d\Phi}{d\Delta x} \simeq C_0 \left( \frac{\Delta x}{H} \right)^k, \qquad (15)$$

where $C_0$ is a constant. Note that the shape for $d\Phi/d\Delta x$ and $d\Phi/d\Delta y$ is very similar. For $\Delta y$ a fit between $3H \leqslant \Delta y \leqslant 20H$ gives $k \approx -1.2$. We can also calculate the general loop distribution function for $\Delta L = (\Delta x^2 + \Delta y^2)^{1/2}$. It almost overlaps with the $d\Phi/d\Delta y$ curve because the loops are nearly toroidal, and a fit between $3H \leqslant \Delta y \leqslant 20H$ gives $k \approx -1.2$.

In the model of UG, a slope of $k \sim -2$ corresponds to the limit that reconnection is slow compared to the shear (the dimensionless reconnection parameter $\kappa \sim 0.01$ in UG), and a slope of $k > -1.5$ corresponds to the cases when the total magnetic energy of the corona is dominated by the largest loops ($\kappa < 0.002$). The shallow $k \sim -1.2$ slope measured here then indicates that our numerical models are probably in a slow Sweet–Parker reconnection regime. However, this comparison should not be taken too seriously[3] because our model is ideal MHD and does not explicitly model reconnection. One serious concern is that the coronal reconnection could fall into a fast, collisionless regime which is poorly understood, and not well modeled by our grid scale dissipation.

Lastly we want to comment on several surface effects in our model. These include the $yz$ component of magnetic stress tensor $M_{yz} \equiv -B_y B_z/(4\pi)$, the vertical components of kinetic flux and Poynting flux, and the mass loss rate. Note that these quantities do not necessarily average to zero because of the outflow boundary conditions. We have found that $\langle M_{yz} \rangle$ is nearly zero with temporal fluctuations of amplitude $\leqslant 10^{-4}\rho_0 c_s^2$, much smaller than the dominant $xy$ component $\langle M_{xy} \rangle$. In the steady

state, the vertical energy flux is dominated by the advective part of the Poynting flux, which is on the order of $10^{-4}\rho_0 c_s^3$. This vertical energy flux is only $\sim 1\%$ of the turbulent dissipation rate $Q$ in the disk main body ($Q \sim \alpha\rho_0 c_s^3 \sim 10^{-2}\rho_0 c_s^3$), indicating a weak vertical energy flux.

The disk loses mass through the upper and lower boundaries. In the last 50 orbits, the disk lost $\sim 1.4\%$ of its initial mass. The vertical mass loss rate is not negligible[4] in our $L_z = 10H$ models because of the outflow boundary conditions. However, we have noted a trend in which the vertical mass loss decreases with increasing $L_z$. For example, in our $L_z = 12H$ model the disk lost $\sim 0.64\%$ of its initial mass during the last 50 orbits, giving a mass loss rate half that of the $L_z = 10H$ model. We therefore expect a decreasing mass loss rate as $L_z$ increases.

It is also worth noting that in our models the mean vertical magnetic fields maintain $\langle B_z \rangle = 0$ because of the shearing box boundary conditions. We also found that the plane-averaged $[B_z] \sim 0$ at all $z$ including at the domain boundaries. The vertical field at the surfaces is turbulent with patches of opposite sign field penetrating the boundaries. However, the vertical field here are fluctuations with radial correlation length $<$ a few $H$ and amplitude $\sim$ one order of magnitude smaller than that at the disk midplane. We have not observed a steady magnetic wind and the observed mass loss is probably due to outflow boundaries.

To summarize, in our models we see a weak wind launched from the disk surface. In a steady state both vertical energy and momentum flux are negligible.

### 3.4. Dependence on Model Parameters

Here we give a brief discussion of the saturation dependence on model parameters, including (1) resolution, (2) $L_x$, (3) $L_z$,

---

[3] Although the reconnection rate in the corona might well determine the vertical magnetic energy profile [$E_{B,c}(z)$], simply from a characteristic field curvature argument, where $l(z) \sim [v_a(z)]/\Omega \sim \Delta x(z)$.

[4] The ratio of vertical mass loss rate to the mass accretion rate is

$$\frac{\dot{M}_z}{\dot{M}_r} \sim \frac{\pi r^2 \frac{\delta\Sigma}{\delta t}}{3\pi \Sigma \nu} = \frac{\pi r^2 \frac{\delta\Sigma}{\delta t}}{3\pi \Sigma \frac{\alpha c_s^2}{\Omega}} = \frac{1}{3} \frac{\delta\Sigma}{\Sigma} \frac{1}{\alpha} \left( \frac{r}{H} \right)^2 \frac{1}{\delta t \Omega} \sim 0.001 \left( \frac{r}{H} \right)^2, \quad (16)$$

where $\dot{M}_r$ is the mass accretion rate at the disk radius $r$, $\delta\Sigma$ is the change of disk surface density in $\delta t$, and we have used a disk turbulent viscosity $\nu = \alpha c_s^2/\Omega$. For $r/H = 30$, $\dot{M}_z/\dot{M}_r \sim 1$.

**Table 1**
Model Parameters

| Model | Size | Resolution | $\beta_0$ | $\overline{\langle \alpha \rangle}$ | $\overline{\langle E_{B,|z| \leqslant 2H} \rangle}/\rho_0 c_s^2$ | $\overline{\langle E_{B,|z|>2H} \rangle}/\rho_0 c_s^2$ |
|---|---|---|---|---|---|---|
| std16 | $(16, 20, 10)H$ | $384 \times 256 \times 128$ | 25 | 0.0125 | 0.0121 | 0.00427 |
| s16b | $(16, 20, 10)H$ | $384 \times 256 \times 128$ | 100 | 0.0157 | 0.0152 | 0.00647 |
| s16c | $(16, 20, 12)H$ | $384 \times 256 \times 160$ | 25 | 0.0141 | 0.0125 | 0.00497 |
| s1 | $(1, 20, 10)H$ | $48 \times 256 \times 128$ | 25 | 0.0191 | 0.0171 | 0.00933 |
| s8 | $(8, 20, 10)H$ | $192 \times 256 \times 128$ | 25 | 0.0124 | 0.0115 | 0.00665 |
| s32 | $(32, 20, 10)H$ | $768 \times 256 \times 128$ | 25 | 0.0269 | 0.0270 | 0.0106 |
| s16a | $(16, 20, 10)H$ | $768 \times 512 \times 256$ | 25 | 0.0230 | 0.0181 | 0.0101 |

and (4) initial field strength in terms of plasma parameter $\beta_0$. When exploring parameter space we vary only one parameter at a time unless stated otherwise. Model parameters can be found in Table 1.

1. *Resolution*. In model s16a, we test the convergence properties of our numerical models by doubling the resolution of the fiducial run to $768 \times 512 \times 256$. We run this model to $t_f \sim 75$ orbits. Averaging over the last $\sim 25$ orbits in the saturated state, we found that $\overline{\langle \alpha \rangle} \sim 0.023$, almost double of that in the fiducial run ($\overline{\langle \alpha \rangle} \sim 0.013$); at the highest resolution explored in this work, saturation level continues to increase with resolution. The dynamic range in resolution explored in this work is modest (highest resolution in this work is $\sim 20$–40 zones per $H$) due to the computational demands of the large box.[5] We have also monitored "quality factor" $Q$, where $Q_i \equiv \lambda_{MRI,i}/\Delta x_i = 2\pi v_{a,i}/(\Omega \Delta x_i)$(see a discussion of $Q$ in Noble et al. 2010), the zones per most unstable linear MRI wavelength in our calculations. For the bulk of the disk inside $\pm 2H$ region, our highest resolution run gives a volume and time averaged $Q_y = 33.7$ and $Q_z = 6.8$ in the saturated state, and so by this measure the toroidal field MRI is well resolved while the vertical field MRI is marginally resolved. Of course, the evolution of the disk is not well described by linear theory in the fully turbulent state, so it is not clear whether $Q$ is a good indicator of when MRI-driven turbulence is sufficiently resolved.
It is worth mentioning the convergence properties of shearing box simulations done in smaller boxes: (1) the unstratified box with a net toroidal field, (2) the stratified box with periodic vertical boundary conditions, and (3) the stratified box with outflow boundaries. First, using a similar algorithm in unstratified disk simulations with a mean toroidal field, Guan et al. (2009) reported that in the resolution range 32–256/$H$ saturation energy increases with resolution ($\propto N_x^{1/3}$). They also pointed out that convergence is expected at higher resolution when the energy-containing eddies are resolved. For the stratified disks, Shi et al. (2010) used $L_x = 2H$ stratified shearing box simulations with vertical outflow boundaries and they also found that $\overline{\langle \alpha \rangle}$ increases with resolution and an $\overline{\langle \alpha \rangle} \sim 0.035$ in their highest resolution run at 32/$H$. Recently, stratified disk simulations done in smaller boxes ($L_x \sim H$) and periodic boundary conditions with zero-net flux have demonstrated convergence with $\overline{\langle \alpha \rangle} \sim 0.01$ with a resolution $\sim 32$–128/$H$ using ATHENA code and periodic boundary conditions (Davis et al. 2010). The sustained turbulence may be due to the presence of a mean toroidal field in the disk midplane. Note

that $\overline{\langle \alpha \rangle}$ in their work is normalized with the initial midplane pressure $P_0$, which is normally a factor of a few larger than domain-averaged $\langle P \rangle$ used here. Using the definition in this work, their $\overline{\langle \alpha \rangle} \sim 0.04$. It is therefore possible that in stratified disk simulations, net-toroidal-field and zero-net-flux models will have similar convergence properties. If this is the case, we then expect a convergence at 64–256/$H$ using our ZEUS-type code.[6]

2. $L_x$. For $L_x$, we have carried out runs with $L_x = H, 8H$, and $32H$, denoted by s1, s8, and s32. Time averaging the last 50 orbits in each run, we found that the saturation level in all these runs is close, with $\overline{\langle \alpha \rangle} \sim 0.0191 \pm 0.00453$ when $L_x = H$, $\overline{\langle \alpha \rangle} \sim 0.0124 \pm 0.00116$ when $L_x = 8H$, $\overline{\langle \alpha \rangle} \sim 0.0125 \pm 0.000965$ when $L_x = 16H$, and $\overline{\langle \alpha \rangle} \sim 0.0269 \pm 0.00211$ when $L_x = 32H$, where the numbers after $\pm$ denote standard deviation $\sigma$. The dependence of $\overline{\langle \alpha \rangle}$ on the box size is not clear, however, it is difficult to measure $\overline{\langle \alpha \rangle}$ in the $L_x = H$ box because of the large fluctuations. In runs with $L_x \geqslant 8H$, the $\sigma$-to-mean ratio is around 0.07–0.09, while $L_x = H$ gives a $\sigma$-to-mean ratio $\sim 0.25$.
Past stratified disk studies (Davis et al. 2010; Shi et al. 2010) have shown that there exist significant (order of unity) long-term fluctuations in $L_x \sim H$ box. The evolution of magnetic energy density in the disk $\langle E_{B,d} \rangle$ for $L_x = H$ and $L_x = 16H$ runs are shown in Figure 8. The smaller fluctuation in large $L_x$ models suggests that (1) parts of the disk with horizontal separation $> H$ are uncorrelated and (2) the volume integration over large-enough domain will smooth out these local fluctuations.
What have we learned in these large domain size models with $L_x \geqslant 10H$? Our $L_x = H$ run is similar to the toroidal model of Miller & Stone (2000). First, in large box runs, the plane-averaged vertical disk structures are similar to those in smaller box runs: we have observed a gas-pressure-supported disk with a Gaussian density profile inside $\sim 2H$ and an extended magnetic-dominated corona outside $\sim 2H$. Second, the long-term average of disk turbulence saturation level is also very similar to the $\sim H$ runs, albeit with much smaller temporal fluctuations. Statistically, for saturation measurement purposes, a large domain run can be regarded as a sum of smaller $H$ run, where the temporal and spatial fluctuations are smoothed out by integrating over decorrelated disk regions.
Our models also suggest that a magnetically dominated corona cannot be studied in an $L_x \sim H$ box (if it can be studied in a numerical MHD model at all). In large domain size runs with $L_x \geqslant 10H$ at $|z| > 2H$ we find

---

[5] For example, a $(L_x, L_y, L_z) = (16, 20, 10)H$ run with resolution $768 \times 512 \times 256$ (run s16a) and $t_f \sim 150$ orbits required $\sim 0.5 \times 10^6$ cpu hr on abe cluster at NCSA.

[6] A run of our fiducial run size with a resolution $64/H$ would require $> 5 \times 10^6$ cpu hr on NCSA's abe cluster.
**Figure 8.** Evolution of the disk magnetic energy density $\langle E_{B,d} \rangle$ in models std16 (solid lines) and s1 (dotted lines). Plotted are the mean magnetic energy density in the region $|z| \leqslant 2H$.

**Figure 9.** Evolution of $\langle B_y \rangle$ (solid lines), $\langle E_B \rangle$ (dotted lines), and $\langle W_{xy} \rangle$ (dashed lines) at $|z| \leqslant 2H$ in model s32. The oscillation period for $\langle B_y \rangle$ is twice that of $\langle E_B \rangle$ and $\langle W_{xy} \rangle$. These temporal oscillations may be caused by a mean field dynamo.

features in the magnetic field correlation function on scales of $\sim 10H$, indicating the existence of mesoscale structure. Although the magnitude of the mass, angular momentum, and energy transport in the corona is small compared with that in the central disk, the corona and the central disk are dynamically connected and large-scale structure in magnetically dominated upper layers may still influence the spatial correlations/structures of the disk below (we will explore this issue in a forthcoming paper). Therefore, in accretion disk models where the spatial structure of the corona is important, such as phenomenological models for accretion disk coronae (e.g., the statistical model of Uzdensky & Goodman 2008) and disk spectra calculations, the radial extent of the corresponding numerical simulation may require an $L_x \geqslant 10H$.

3. $L_z$. We have investigated the effect of vertical boundaries by running a model (s16c) with $L_z = 12H$. We find no qualitative difference between the $L_z = 12H$ and $L_z = 10H$ models: the saturation $\overline{\langle \alpha \rangle} \sim 0.0141$, $\overline{\langle E_{B,d} \rangle}/\rho_0 c_s^2 \sim 0.0125$, and $\overline{\langle E_{B,c} \rangle}/\rho_0 c_s^2 \sim 0.00497$, all within $\sim 10\%$ of the fiducial model. We also obtain a similar vertical disk structure when $L_z$ increases: inside $2.5H$ the disk has a well-fitted Gaussian $\overline{[\rho]}(z)$ and a flat $\overline{[E_B]}(z)$; outside $2.5H$ the corona extends to $|a| = \pm 6H$ in model s16c. Both $\overline{[\rho]}(z)$ and $\overline{[E_B]}(z)$ also have an exponential profile, but the fitted coronal exponential scale height increases $\sim 20\%$ compared to the fiducial model. The coronal loop distribution functions are almost identical to those of the fiducial model, which is not surprising considering the steep decline of $d\Phi/d\Delta z_{max}$ as $\Delta z_{max}$ exceeds $\sim H$. As discussed before, some caution is needed in interpreting this vertical extension of corona structure with increasing domain size: our calculation is essentially an MHD calculation, whereas real disk coronae are probably force free and also influenced by non-ideal plasma effects (e.g., reconnection) that are ill modeled in our numerical scheme.
4. $\beta_0$. We have tested the effect of initial field strength on the saturation level. In most of our runs we start from a uniform toroidal field inside the disk with $\beta_0 = 25$. We then carry out a comparison run s16b with the same field geometry but weaker strength $\beta_0 = 100$. We find that turbulence saturates at the similar level using weaker initial field strength, with $\overline{\langle \alpha \rangle} \sim 0.0157$, $\overline{\langle E_{B,d} \rangle}/\rho_0 c_s^2 \sim 0.0152$, and $\overline{\langle E_{B,c} \rangle}/\rho_0 c_s^2 \sim 0.00647$, therefore in stratified disks the saturation does not depend on the initial field strength. In comparison, in unstratified disk models $\langle E_B \rangle$ is found to scale with the initial mean field strength $\langle B_y \rangle$[7] (see a detailed discussion in Guan et al. 2009). The important difference here lies in the stratification and the accompanying outflow boundary conditions, which allow changes in mean toroidal field strength in the turbulent disk. The stratified disk model then allows the disk to adjust its net flux and field strength in a self-consistent way. It is worth pointing out that the saturation level is a volume average over large scales where different parts of the disk decorrelate; on the scale where the turbulence is localized ($\leqslant H$), it is still possible that the local saturation $\langle E_{B,d} \rangle_{local} \propto \langle B_{y,d} \rangle_{local}$. Does the saturation level depend on the instantaneous mean field strength in the stratified disk? The evolution of the mean azimuthal field $\langle B_{y,d} \rangle$ in the region $|z| \leqslant 2H$ in model s32 is plotted in Figure 9. The mean field does not have a fixed value and changes signs over a time scale of $\sim 10$ orbits. Averaging the last 100 orbits, the mean magnitude of toroidal field strength in the turbulent disk region is $\overline{|\langle B_y \rangle|} \sim 0.012\sqrt{4\pi}\rho_0^{1/2}c_s$, therefore there is weak net toroidal field in the turbulent disk region to drive MRI. The figure also shows the evolution of the mean magnetic

---

[7] Guan et al. (2009) found a linear relation between $\langle B_y \rangle_d$ and the saturation $\overline{\alpha} \propto \overline{\langle E_B \rangle} \propto \rho_0 c_s V_{A,y0}$, where $V_{A,y0} = B_{y0}/(4\pi\rho_0 c_s^2)^{1/2}$ is the mean azimuthal Alfvén speed. This result is also consistent with scalings obtained from earlier work (e.g., Hawley et al. 1995).
**Figure 10.** Butterfly diagram for $[E_B]$ in model s32.
(A color version of this figure is available in the online journal.)

energy density $\langle E_{B,d} \rangle$ and mean $xy$ stress $\langle W_{xy,d} \rangle$ in the same run. Both $\langle E_{B,d} \rangle$ and $\langle W_{xy,d} \rangle$ have a fixed overall saturation level with a superimposed small oscillation with a period half of that of $\langle B_y \rangle$. Again, this is dramatically different from the unstratified disk, where the saturation level is proportional to the mean field strength. The overall saturation level in a stratified disk is *not* determined by the instantaneous mean field strength nor by the initial field strength.

On the other hand, as shown in Figure 9, the oscillations of $\langle B_y \rangle$ and $\langle E_{B,d} \rangle$ are closely correlated and oscillation period for $\langle B_y \rangle$ is twice that of $\langle E_{B,d} \rangle$. This suggests that $\langle B^2 \rangle$ is correlated with $\langle B_y \rangle$, even though $\langle B_y \rangle \ll \langle B^2 \rangle^{1/2}$. Therefore, the saturation level may be determined both by the MRI induced by the mean toroidal field in the turbulent disk region and magnetic buoyancy effects (e.g., Vishniac 2009).

### 4. BUTTERFLY DIAGRAM: A MEAN DYNAMO IN THE DISK?

One interesting feature appearing in all our models is an oscillation of the mean magnetic energy on a timescale of a few orbits. As an example, we plot the "butterfly" diagram for model s32 in Figure 10, which illustrates the evolution of $[E_B](z)$. This bears a superficial resemblance to the famous butterfly diagram observed in solar activity cycles.

We use Fourier analysis to determine the period of butterfly diagram. Using data $\int dy E_B(|z| = 2.5H; x, t)$, taken from two layers with $|z| \sim 2.5H$ and have been averaged in the $y$-direction to improve statistics, we perform a two-dimensional fast Fourier transform (in $x$ and $t$) on the data set. The normalized temporal power spectral density (PSD) for $[E_{B,|z|=2.5H}]$ in model s32 is shown in Figure 11. Here we have plotted a cut through $k_x = 0$ plane in the two-dimensional $k_x - f$ PSD map. We have also checked that the different sides of the disk have very similar PSD and we have plotted the sum of contribution from both layers. The arrow in the figure marks the peak frequency in the PSD. This frequency, $f \sim 0.03\,\Omega$, corresponds to the period of the butterfly diagram for $[E_B]$.

The PSD has $P \sim f^k$, with $k \sim -2.3$. Interestingly, results from recent global GRMHD simulations (Noble & Krolik 2009) suggest that the slope for the coronal luminosity temporal power spectrum is $k \sim -2$, almost independent of model parameters and very close to what has been observed at high frequency in black hole accretion disk systems. The power-law index for the temporal power spectrum from local and global simulations is therefore remarkably close, considering that we are only calculating the temporal spectrum for coronal magnetic energy density.

**Figure 11.** Normalized temporal power spectral density for $[E_B]$ in model s32. The data are taken from the layers with $|z| \sim 2.5H$. We also draw the best-fit $k = -2.3$ slope for the temporal PSD. The arrow marks the peak frequency in the power spectrum. This frequency, $f \sim 0.03\,\Omega$, corresponds to the period of the butterfly diagram for $[E_B]$.

The period for $[E_B]$ is $P_{[E_B]} \sim 5$ orbits. Besides $[E_B]$, one could also plot butterfly diagrams for $[W_{xy}]$ and $[B_y]$. The period for $[W_{xy}]$ is the same as that of $[E_B]$, $\sim 5$ orbits, while the period for $[B_y]$ is twice that of $[E_B]$, $P_{[B_y]} \sim 10$ orbits, because of the reversal of mean fields (see Figure 9).

For $[E_B]$, we find $P_{\langle E_B \rangle} \sim 5$ orbits in all our models. This quasi-periodicity has appeared in all the stratified shearing box simulations that we are aware of, even in those with periodic vertical boundary conditions (Davis et al. 2010). Interestingly, Reynolds & Fabian (2008) have also obtained similar butterfly diagrams at certain radii (e.g., $r = 8r_g$ and $r = 10r_g$, where $r_g \equiv GM/c^2$ is the gravitational radii) in their global pseudo-Newtonian thin disk simulations. It would be of interest in the future to test (1) whether the butterfly diagram is simply a local feature at a certain location on the disk (as in shearing box simulations) or this quasi-periodicity can be coherent and sustained over a large radial range and (2) what model parameter(s) the period depends on.

The butterfly diagram together with the reversal of the mean fields (for both the dominant toroidal field and a weak radial field) in the disk may be modeled by a mean field dynamo of

$\tilde{\alpha}$ type (e.g., Moffatt 1978[8]). In the rest of this section, we will present a toy model to give a qualitative description of these oscillations.

Let us first consider two important dynamical processes in a stratified disk: (1) the MRI-driven turbulence, which draws free energy of rotation and operates on the orbital timescale $\sim \Omega^{-1}$; and (2) magnetic buoyancy, which operates on the local Alfvén timescale $\tau_A \sim H/[\delta v_A^2]^{1/2}$. In our simulations, we found in the disk region $|z| \leqslant 2H$ the magnetic energy density is almost a constant with height, with $[E_B] \geqslant 10^{-2}\rho_0 c_s^2$, which gives an average magnetic buoyancy timescale $\tau_A \leqslant$ a few $\Omega^{-1}$ inside the disk. The period of the butterfly diagram is much longer than these two timescales. Therefore, these two processes alone cannot describe the dynamics represented in butterfly diagrams.

The $\tilde{\alpha}$-type mean dynamo equations for the disk mean fields $\langle B_x \rangle$ and $\langle B_y \rangle$ can be derived from averaging the induction equation, $\partial_t \langle \boldsymbol{B} \rangle = \langle \nabla \times (\boldsymbol{v} \times \boldsymbol{B}) \rangle$, here $\langle \rangle$ denotes ensemble averages. Assuming the turbulent EMF, $\boldsymbol{\varepsilon}$ is related to the mean field with a dynamo parameter $\tilde{\alpha}_i$, $\langle \boldsymbol{\varepsilon} \rangle \equiv \langle \delta \boldsymbol{v} \times \delta \boldsymbol{B} \rangle = \tilde{\alpha}_i \langle \boldsymbol{B}_i \rangle$, one simple form of dynamo equations in a stratified thin Keplerian disk is (cf. Equations (5) and (6) in Vishniac & Brandenburg 1997),

$$\partial_t \langle B_y \rangle = -\frac{3}{2}\Omega\langle B_x \rangle - \partial_z(\langle v_b \rangle\langle B_y \rangle) + \partial_z(\tilde{\alpha}_1\langle B_x \rangle) \quad (17)$$

and

$$\partial_t B_x = -\partial_z(\langle v_b \rangle\langle B_x \rangle) - \partial_z(\tilde{\alpha}_2\langle B_y \rangle) , \quad (18)$$

where $v_b$ is a characteristic vertical velocity induced by magnetic buoyancy. In Equation (17), the first term is the shear term, the second term denotes buoyancy due to the mean field, and the last term is the mean field dynamo term. Only $\partial_z$ terms are retained because the disk is thin. For simplicity, we have also dropped the diffusion terms (for a discussion on these terms, see a recent study by Gressel 2010). We then take $\partial_z \sim 1/(2H)$ and $v_b \approx |v_A| \equiv |B|/\sqrt{4\pi\rho_0} \sim |B_y|/\sqrt{4\pi\rho_0}$, where $|v_A|$ is the mean Alfvén speed. Equations (17) and (18) then become

$$\frac{dB_y}{dt} = -\frac{3}{2}\Omega B_x - \frac{|v_A|}{2H}B_y + \frac{\tilde{\alpha}_1}{2H}B_x \quad (19)$$

and

$$\frac{dB_x}{dt} = -\frac{|v_A|}{2H}B_x - \frac{\tilde{\alpha}_2}{2H}B_y . \quad (20)$$

For clarity, we have dropped $\langle \rangle$ in the above equations. Note that Equations (19) and (20) have no spatial dependence. Taken together, they are coupled ordinary differential equations and can be solved numerically given initial conditions for $B_y$ and $B_x$.

In Figure 12, we plot one solution for this toy model. This solution is obtained by integrating the above equations from an initially pure toroidal field with $\beta_0 \sim 22$ and by choosing $\tilde{\alpha}_1 = \tilde{\alpha}_2 = -0.01$.[9] The period for $B_y$ in this particular toy model is $\sim 10$ orbits. The magnitude of $\tilde{\alpha}$ controls the oscillation frequency: in general, larger $|\tilde{\alpha}|$ leads to smaller period, although the scaling is not linear. Initial conditions have little effect on the evolution in our toy model. In conclusion, the butterfly diagram and the mean field reversal observed in these simulations may imply a mean field dynamo at work in stratified disks.

---

[8] In this work, we use $\tilde{\alpha}$ to denote dynamo model type. It should not be confused with the accretion disk turbulence level parameter $\alpha$.

[9] By definition, $\tilde{\alpha}_1 = \frac{\langle \varepsilon_x \rangle}{\langle B_x \rangle} = \frac{\langle \delta v_y \delta B_z - \delta v_z \delta B_y \rangle}{\langle B_x \rangle}$ and $\tilde{\alpha}_2 = \frac{\langle \varepsilon_y \rangle}{\langle B_y \rangle} = \frac{\langle \delta v_z \delta B_x - \delta v_x \delta B_z \rangle}{\langle B_y \rangle}$. In principle, $\tilde{\alpha}_1$ does not necessarily equal $\tilde{\alpha}_2$ due to anisotropy.

**Figure 12.** Evolution of $B_y$ (solid lines) and $B_x$ (dotted lines) in our mean field dynamo toy model. $\alpha_1 = \alpha_2 = -0.01$ in the plotted model.

Does it make sense to identify these oscillations with observed QPOs? In a Keplerian disk, the orbital frequency at $r$ is $f_{\rm orb} = 1/(2\pi)(GM)^{1/2}r^{-3/2}$. The QPO frequency is $f_{\rm QPO} = 1/5f_{\rm orb} \approx 20 \times (r/10M)^{-3/2}(M/10\,M_\odot)^{-1}$Hz. Our disk model represents a geometrically thin, optically thick disk. This is most easily understood as corresponding to the high soft state in black hole X-ray binaries, which is dominated by a thermal component. For a $10\,M_\odot$ black hole, a 5Hz QPO (e.g., XTE J1550$-$564) corresponds to $r_{\rm in} \sim 25M$, which is far from the innermost region of a thin disk where most of the thermal X-ray emissions presumably originate. This oscillation frequency may be sensitive to the disk vertical structure (e.g., if the disk is not isothermal), and therefore may exhibit a much more complex behavior in real disks, in which the vertical structure is closely coupled to vertical energy transport. On the other hand, observations indicate that QPOs are absent or very weak in the thermal state, but may appear in the very high state when a sizable thermal disk component is present, although the QPOs are more associated with Comptonizing electrons (Remillard & McClintock 2006); it is difficult to associate the butterfly oscillations with observed QPO phenomena.

## 5. SUMMARY AND DISCUSSION

We have carried out stratified shearing box simulations with domain size $L_x = H$ to $L_x = 32H$ to study properties of isothermal accretion disks on a scale larger than the disk scale height $H$. Our numerical models have vertical extent $\geqslant 5H$ above and below the disk midplane with outflow boundary conditions. All models start from a net mean toroidal field in the central disk region and the mean fields are allowed to change in the evolution.

We find the disk has an oscillating mean toroidal field and $\overline{\langle \alpha \rangle} \sim 0.012$–$0.025$ in the parameter range we explored. We have not found a clear dependence of $\overline{\langle \alpha \rangle}$ on $L_x$ in our models, although the temporal variances in volume-averaged quantities decrease with $L_x$. The highest resolution used here is modest (20–40 zones per $H$), and we have observed $\overline{\langle \alpha \rangle}$

increases with resolution. Recently, Davis et al. (2010) report a converged $\overline{\langle\alpha\rangle} \sim 0.04$ in $L_x \sim H$ high-resolution stratified disk simulations with zero-net-flux and periodic vertical boundary conditions (so that the volume-averaged field cannot change during the evolution). The sustained turbulence may be due to the presence of a mean toroidal field in the region close to the disk midplane, lending plausibility to the idea that the saturation mechanism of MRI in stratified disks near the midplane is similar to that in unstratified disks with a net toroidal field.

In the saturated state, the disk vertical structure consists of (1) a turbulent disk at $|z| \leqslant 2H$ and (2) a magnetically dominated upper region at $|z| > 2H$, confirming earlier small ($L_x \sim H$) box results.

At $|z| \leqslant 2H$, the disk is mainly supported by gas pressure, and a Gaussian density profile is observed. The plane-averaged magnetic energy density $[E_B](z)$ and Maxwell stress $[M_{xy}](z)$ are nearly uniform with vertical height $z$ in this region, where the disk is marginally stable to the Parker instability. At $|z| > 2H$, exponential dependences on $z$ are observed for both $[\rho]$ and $[E_B]$. Fitting formulae for $[\rho](z)$ and $[E_B](z)$ are given in Equations (7) and (8), respectively.

Using a two-point correlation function analysis, we found that close to the midplane, the disk is dominated by small-scale ($\leqslant H$) turbulence, very similar to what we have observed in unstratified disk models. In the corona, magnetic fields are correlated on scales of $\sim 10H$, implying the existence of mesoscale structures. Recently, Johansen et al. (2009) have also observed large-scale pressure and zonal flow structures in their large shearing box simulations. We will give a detailed report of mesoscale structure in isothermal disks in a forthcoming paper.

We have adopted a statistical approach to study the geometry of coronal magnetic fields. Only $\approx 4\%$ of coronal field lines are open. For closed field lines, we calculated the magnetic loop distribution function for the loop foot separation $\Delta\boldsymbol{x}$ in the $x$–$y$ plane, loop maximum height $\Delta z_{\max}$, and loop orientation angle $\theta_{\mathrm{foot}}$. The loops are dominantly toroidal due to the differential shear. The loop foot distribution between $H$ and $20H$ is a power law with an index $k \sim -1.25$. In the phenomenological model of UG, this corresponds to the limit where reconnection is slow compared to the shear. These comparisons are limited because our models are working in an ideal MHD regime and reconnection is purely numerical.

In our models, both vertical energy and momentum flux are negligible in the steady state. The mass loss rate from the disk surface is small and decreases with increasing $L_z$. The surface effects are therefore minimal and indicate a lack of disk winds in our stratified disk models. The weak winds are consistent with the constraint that we have a zero-net vertical magnetic flux in these models. A Blandford–Payne-type wind requires the existence of a vertical net field (e.g., see Suzuki & Inutsuka 2009), although we note that in their models the most unstable wavelength for the extremely weak field is probably not resolved. Initial investigations show that even a weak ($\beta_0 \sim 1600$) net $z$ field will induce very violent accretion in stratified shearing box models: at certain regions of the disk accretion will run away, eventually causing the disk break into rings. Similar phenomena were reported in net vertical field models of Miller & Stone (2000).

We have confirmed the "butterfly" diagram seen in earlier stratified disk models of size $L_x \sim H$. The butterfly diagrams persist even in our largest runs with $L_x = 32H$. We also report the reversal of the mean fields (for both the dominant toroidal field and a weak radial field) in the disk on a timescale twice that of $[E_B]$. The periods for the butterfly diagram are close in all our models, $P \sim 5$ orbits for $[E_B]$ and $P \sim 10$ orbits for $[B_y]$. The mean field reversal and butterfly diagram may indicate the existence of a mean field dynamo in stratified disks, perhaps controlled by the MRI and magnetic buoyancy. We have presented a toy model for an $\tilde{\alpha}$-type mean field dynamo in stratified disks and found that an $\tilde{\alpha}_{\mathrm{imp}} \sim 0.01$ will produce the reported period. Further exploration of parameter dependences would be useful for analytical modeling. In the future, it would also be interesting to test whether the butterfly oscillations persist when averaging over a large range of radii in global disk simulations. The butterfly diagram may be associated with low frequency QPOs and therefore a good observational diagnostic for accretion flows. On the other hand, we also report a power-law index $k \sim -2.3$ in the temporal power spectrum for coronal magnetic energy fluctuations, consistent with results from recent GRMHD black hole accretion disk simulations.

Our stratified disk models are primarily limited by the assumption that the disk is isothermal. Effects of thermodynamics and radiation therefore are neglected in this work. Our models are also limited by finite resolution, box size, evolution time, and the absence of explicit dissipation. Additional insights may also be provided by the future explorations on magnetic field strength and geometry in disks.
