Abstract
The goal of the Laser Interferometric Gravitational-Wave Observatory (LIGO) is to detect and study gravitational waves (GWs) of astrophysical origin. Direct detection of GWs holds the promise of testing general relativity in the strong-field regime, of providing a new probe of exotic objects such as black holes and neutron stars and of uncovering unanticipated new astrophysics. LIGO, a joint Caltech–MIT project supported by the National Science Foundation, operates three multi-kilometer interferometers at two widely separated sites in the United States. These detectors are the result of decades of worldwide technology development, design, construction and commissioning. They are now operating at their design sensitivity, and are sensitive to gravitational wave strains smaller than one part in 10^{21}. With this unprecedented sensitivity, the data are being analyzed to detect or place limits on GWs from a variety of potential astrophysical sources.

1. Introduction
The prediction of gravitational waves (GWs), oscillations in the space–time metric that propagate at the speed of light, is one of the most profound differences between Einstein’s general theory of relativity and the Newtonian theory of gravity that it replaced. GWs remained a theoretical prediction for more than 50 years until the first observational evidence for their existence came with the discovery and subsequent observations of the binary pulsar PSR 1913 + 16, by Russell Hulse and Joseph Taylor. This is a system of two neutron stars (NSs) that orbit each other with a period of 7.75 h. Precise timing of radio pulses emitted by one of the NSs, monitored now over several decades, shows that their orbital period is slowly decreasing at just the rate predicted for the general-relativistic emission of GWs [1]. Hulse and Taylor were awarded the Nobel Prize in Physics for this work in 1993.

In about 300 million years, the PSR 1913 + 16 orbit will decrease to the point where the pair coalesces into a single compact object, a process that will produce directly detectable GWs. In the meantime, the direct detection of GWs will require similarly strong sources—extremely large masses moving with large accelerations in strong gravitational fields. The goal of LIGO, the Laser Interferometer Gravitational-Wave Observatory [2], is just that: to detect and study GWs of astrophysical origin. Achieving this goal will mark the opening of a new window on the universe, with the promise of new physics and astrophysics. In physics, GW detection could provide information about strong-field gravitation, the untested domain of strongly curved space where Newtonian gravitation is no longer even a poor approximation. In astrophysics, the sources of GWs that LIGO might detect include binary NSs (like PSR 1913 + 16 but much later in their evolution); binary systems where a black hole (BH) replaces one or both of the NSs; a stellar core collapse which triggers a type II supernova; rapidly rotating, non-axisymmetric NSs; and possibly processes in the early universe that produce a stochastic background of GWs [3].

In the past few years the field has reached a milestone, with decades-old plans to build and operate large interferometric GW detectors now realized in several locations worldwide. This paper focuses on LIGO, which operates the most sensitive detectors yet built. We aim to describe the LIGO detectors and how they operate, explain how they have achieved their remarkable sensitivity and review how their data can be used to learn about a variety of astrophysical phenomena.
2. Gravitational waves

The essence of general relativity is that mass and energy produce a curvature of four-dimensional space–time, and that matter moves in response to this curvature. The Einstein field equations prescribe the interaction between mass and space–time curvature, much as Maxwell’s equations prescribe the relationship between electric charge and electromagnetic fields. Just as electromagnetic waves are time-dependent vacuum solutions to Maxwell’s equations, GWs are time-dependent vacuum solutions to the field equations. GWs are oscillating perturbations to a flat, or Minkowski, space–time metric, and can be thought of equivalently as an oscillating strain in space–time or as an oscillating tidal force between free test masses.

As with electromagnetic waves, GWs travel at the speed of light and are transverse in character, i.e. the strain oscillations occur in directions orthogonal to the direction in which the wave is propagating. Whereas electromagnetic waves are dipolar in nature, GWs are quadrupolar: the strain pattern contracts space along one transverse dimension, while expanding it along the orthogonal direction in the transverse plane (see figure 1). Gravitational radiation is produced by oscillating multipole moments of the mass distribution of a system. The principle of mass conservation rules out monopole radiation, and the principles of linear and angular momentum conservation rule out gravitational dipole radiation. Quadrupole radiation is the lowest allowed form and is thus usually the dominant form. In this case, the GW field strength is proportional to the second time derivative of the quadrupole moment of the source, and it falls off in amplitude inversely with distance from the source. The tensor character of gravity—the hypothetical graviton is a spin-2 particle—means that the transverse strain field comes in two orthogonal polarizations. These are commonly expressed in a linear polarization basis as the ‘+’ polarization, reflecting the fact that they are rotated 45° relative to one another. An astrophysical GW will, in general, be a mixture of both polarizations.

GWs differ from electromagnetic waves in that they propagate essentially unperturbed through space, as they interact only very weakly with matter. Furthermore, GWs are intrinsically non-linear, because the wave energy density itself generates additional curvature of space–time. This phenomenon is only significant, however, very close to strong sources of waves, where the wave amplitude is relatively large. More usually, GWs distinguish themselves from electromagnetic waves by the fact that they are very weak. One cannot hope to detect any waves of terrestrial origin, whether naturally occurring or manmade; instead one must look for very massive compact astrophysical objects, moving at relativistic velocities. For example, strong sources of GWs that may exist in our galaxy or nearby galaxies are expected to produce wave strengths on Earth that do not exceed strain levels of one part in \(10^{-21}\). Finally, it is important to appreciate that GW detectors respond directly to GW amplitude rather than GW power; therefore the volume of space that is probed for potential sources increases as the cube of the strain sensitivity.

Figure 1. A GW traveling perpendicular to the plane of the diagram is characterized by a strain amplitude \(h\). The wave distorts a ring of test particles into an ellipse, elongated in one direction in one half-cycle of the wave, and elongated in the orthogonal direction in the next half-cycle. This oscillating distortion can be measured with a Michelson interferometer oriented as shown. The length oscillations modulate the phase shifts accrued by the light in each arm, which are in turn observed as light intensity modulations at the photodetector (green semi-circle). This depicts one of the linear polarization modes of the GW.

3. LIGO and the worldwide detector network

As illustrated in figure 1, the oscillating quadrupolar strain pattern of a GW is well matched by a Michelson interferometer, which makes a very sensitive comparison of the lengths of its two orthogonal arms. LIGO utilizes three specialized Michelson interferometers, located at two sites (see figure 2): an observatory on the Hanford site in Washington houses two interferometers, the 4 km-long H1 and 2 km-long H2 detectors; and an observatory in Livingston Parish, Louisiana, houses the 4 km-long L1 detector. Other than the shorter length of H2, the three interferometers are essentially identical. Multiple detectors at separated sites are crucial for rejecting instrumental and environmental artifacts in the data, by requiring coincident detections in the analysis. Also, because the antenna pattern of an interferometer is quite wide, source localization requires triangulation using three separated detectors.

The initial LIGO detectors were designed to be sensitive to GWs in the frequency band 40–7000 Hz, and capable of detecting a GW strain amplitude as small as \(10^{-21}\) [2]. With funding from the National Science Foundation, the LIGO sites and detectors were designed by scientists and engineers from the California Institute of Technology and the Massachusetts Institute of Technology, constructed in the late 1990s, and commissioned over the first 5 years of this decade. From November 2005 to September 2007, they operated at their design sensitivity in a continuous data-taking mode. The data from this science run, known as S5, are being analyzed for a variety of GW signals by a group of researchers known as the LIGO Scientific Collaboration [4]. At the most sensitive frequencies, the instrument root-mean-square (rms) strain noise has reached an unprecedented level of \(3 \times 10^{-22}\) in a 100 Hz band.

Although in principle LIGO can detect and study GWs by itself, the potential to do astrophysics can be quantitatively and qualitatively enhanced by operation in a more extensive network. For example, the direction of travel of the GWs and
the complete polarization information carried by the waves can only be extracted by a network of detectors. Such a global network of GW observatories has been emerging over the past decade. In this period, the Japanese TAMA project built a 300 m interferometer outside Tokyo, Japan [5]; the German–British GEO project built a 600 m interferometer near Hanover, Germany [6]; and the European Gravitational Observatory built the 3 km-long interferometer Virgo near Pisa, Italy [7]. In addition, plans are underway to develop a large scale GW detector in Japan sometime during the next decade [8].

Early in its operation LIGO joined with the GEO project; for strong sources the shorter, less sensitive GEO 600 detector provides added confidence and directional and polarization information. In May 2007 the Virgo detector began joint observations with LIGO, with a strain sensitivity close to that of LIGO’s 4 km interferometers at frequencies above ∼1 kHz. The LIGO Scientific Collaboration and the Virgo Collaboration negotiated an agreement that all data collected from that date are to be analyzed and published jointly.

4. Detector description

Figure 1 illustrates the basic concept of how a Michelson interferometer is used to measure a GW strain. The challenge is to make the instrument sufficiently sensitive: at the targeted strain sensitivity of 10⁻²¹, the resulting arm length change is only ∼10⁻¹⁸ m, a thousand times smaller than the diameter of a proton. Meeting this challenge involves the use of special interferometry techniques, state-of-the-art optics, highly stable lasers and multiple layers of vibration isolation, all of which are described in the sections that follow. And of course a key feature of the detectors is simply their scale: the arms are made as long as practically possible to increase the signal due to a GW strain. See table 1 for a list of the main design parameters of the LIGO interferometers.

4.1. Interferometer configuration

The LIGO detectors are Michelson interferometers whose mirrors also serve as gravitational test masses. A passing GW will impress a phase modulation on the light in each arm of the Michelson, with a relative phase shift of 180° between the arms. When the Michelson arm lengths are set such that the un-modulated light interferes destructively at the anti-symmetric (AS) port—the dark fringe condition—the phase modulated sideband light will interfere constructively, with an amplitude proportional to GW strain and the input power. With dark fringe operation, the full power incident on the beamsplitter is returned to the laser at the symmetric port. Only differential motion of the arms appears at the AS port; common mode signals are returned to the laser with the carrier light.

Two modifications to a basic Michelson, shown in figure 3, increase the carrier power in the arms and hence the GW sensitivity. First, each arm contains a resonant Fabry–Perot optical cavity made up of a partially transmitting input mirror and a high reflecting end mirror. The cavities cause the light to effectively bounce back and forth multiple times in the arms, increasing the carrier power and phase shift for a given strain amplitude. In the LIGO detectors the Fabry–Perot cavities multiply the signal by a factor of 100 for a 100 Hz GW. Second, a partially reflecting mirror is placed between the laser and beamsplitter to implement power recycling [9]. In this technique, an optical cavity is formed between the power recycling mirror and the Michelson symmetric port. By matching the transmission of the recycling mirror to the optical losses in the Michelson, and resonating this recycling cavity, the laser power stored in the interferometer can be significantly increased. In this configuration, known as a power recycled Fabry–Perot Michelson, the LIGO interferometers increase the power in the arms by a factor of ≈8000 with respect to a simple Michelson.

4.2. Laser and optics

The laser source is a diode-pumped, Nd : YAG master oscillator and power amplifier system, and emits 10 W in a single frequency at 1064 nm [10]. The laser power and frequency are actively stabilized, and passively filtered with a transmissive ring cavity (pre-mode cleaner, PMC). The laser power stabilization is implemented by directing a sample of the beam to a photodetector, filtering its signal and feeding it back to the power amplifier; this servo stabilizes the relative power.
Table 1. Parameters of the LIGO interferometers. H1 and H2 refer to the interferometers at Hanford, Washington, and L1 is the interferometer at Livingston Parish, Louisiana.

Figure 3. Optical and sensing configuration of the LIGO 4 km interferometers (the laser power numbers here are generic; specific power levels are given in table 1). The IO block includes laser frequency and amplitude stabilization, and electro-optic phase modulators. The power recycling cavity is formed between the PRM and the two ITMs, and contains the BS. The inset photo shows an input test mass mirror in its pendulum suspension. The near face has a highly reflective coating for the infrared laser light, but transmits visible light. Through it one can see mirror actuators arranged in a square pattern near the mirror perimiter.

fluctuations of the beam to $\sim 10^{-7} \text{ Hz}^{-1/2}$ at 100 Hz [11]. The laser frequency stabilization is done in multiple stages that are more fully described in later sections. The first, or pre-stabilization stage, uses the traditional technique of servo locking the laser frequency to an isolated reference cavity using the Pound–Drever–Hall (PDH) technique [12], in this case via feedback to frequency actuators on the master oscillator and to an electro-optic phase modulator. The servo bandwidth is 500 kHz, and the pre-stabilization achieves a stability level of $\sim 10^{-5} \text{ Hz}^{-1/2}$ at 100 Hz. The PMC transmits the pre-stabilized beam, filtering out both any light not in the fundamental Gaussian spatial mode and laser noise at frequencies above a few megahertz [13]. The PMC output beam is weakly phase-modulated with two radio-frequency (RF) sine waves, producing, to first-order, two pairs of sideband fields around the carrier field; these RF sideband fields are used in a heterodyne detection system described below.

After phase modulation, the beam passes into the LIGO vacuum system. All the main interferometer optical components and beam paths are enclosed in the ultra-high vacuum system ($10^{-8} - 10^{-9}$ Torr) for acoustical isolation and to reduce phase fluctuations from light scattering off residual gas [14]. The long beam tubes are particularly noteworthy components of the LIGO vacuum system. These 1.2 m diameter, 4 km long stainless steel tubes were designed to have low-outgassing so that the required vacuum could be attained by pumping only from the ends of the tubes. This was achieved by special processing of the steel to remove hydrogen, followed by an in situ bakeout of the spiral-welded tubes, for approximately 20 days at 160 °C.

The in-vacuum beam first passes through the mode cleaner (MC), a 12 m long, vibrationally isolated transmissive ring cavity. The MC provides a stable, diffraction-limited beam with additional filtering of laser noise above several kilohertz [15], and it serves as an intermediate reference for frequency stabilization. The MC length and modulation frequencies are matched so that the main carrier field and the modulation sideband fields all pass through the MC. After the MC is a Faraday isolator and a reflective 3-mirror telescope that expands the beam and matches it to the arm cavity mode.

The interferometer optics, including the test masses, are fused-silica substrates with multilayer dielectric coatings, manufactured to have extremely low scatter and low
absorption. The test mass substrates are polished so that the surface deviation from a spherical figure, over the central 80 mm diameter, is typically 5 Å or smaller, and the surface microroughness is typically less than 2 Å [16]. The mirror coatings are made using ion-beam sputtering, a technique known for producing ultralow-loss mirrors [17, 18]. The absorption level in the coatings is generally a few parts-per-million (ppm) or less [19], and the total scattering loss from a mirror surface is estimated to be 60–70 ppm.

In addition to being a source of optical loss, scattered light can be a problematic noise source, if it is allowed to reflect or scatter from a vibrating surface (such as a vacuum system wall) and recombine with the main beam [20]. Since the vibrating, re-scattering surface may be moving by ~10 orders of magnitude more than the test masses, very small levels of scattered light can contaminate the output. To control this, various baffles are employed within the vacuum system to trap scattered light [20, 21]. Each 4 km long beam tube contains approximately 200 baffles to trap light scattered at small angles from the test masses. These baffles are stainless steel truncated cones, with serrated inner edges, distributed so as to completely hide the beam tube from the line of sight of any arm cavity mirror. Additional baffles within the vacuum chambers prevent light outside the mirror apertures from hitting the vacuum chamber walls.

4.3. Suspensions and vibration isolation

Starting with the MC, each mirror in the beam line is suspended as a pendulum by a loop of steel wire. The pendulum provides $f^{-2}$ vibration isolation above its eigenfrequencies, allowing free movement of a test mass in the GW frequency band. Along the beam direction, a test mass pendulum isolates by a factor of nearly 2 at 100 Hz. The position and orientation of a suspended optic is controlled by electromagnetic actuators: small magnets are bonded to the optic and coils are mounted to the suspension support structure, positioned to maximize the magnetic force and minimize ground noise coupling. The actuator assemblies also contain optical sensors that measure the position of the suspended optic with respect to its support structure. These signals are used to actively damp eigenmodes of the suspension.

The bulk of the vibration isolation in the GW band is provided by four-layer mass–spring isolation stacks, to which the pendulums are mounted. These stacks provide approximately $f^{-8}$ isolation above ~10 Hz [22], giving an isolation factor of about 10^8 at 100 Hz. In addition, the L1 detector, subject to higher environmental ground motion than the Hanford detectors, employs seismic pre-isolators between the ground and the isolation stacks. These active isolators employ a collection of motion sensors, hydraulic actuators and servo controls; the pre-isolators actively suppress vibrations in the band 0.1–10 Hz, by as much as a factor of 10 in the middle of the band [23].

4.4. Sensing and controls

The two Fabry–Perot arms and power recycling cavities are essential to achieving the LIGO sensitivity goal, but they require an active feedback system to maintain the interferometer at the proper operating point [24]. The round trip length of each cavity must be held to an integer multiple of the laser wavelength so that newly introduced carrier light interferes constructively with light from previous round trips. Under these conditions the light inside the cavities builds up and they are said to be on resonance. In addition to the three cavity lengths, the Michelson phase must be controlled to ensure that the AS port remains on the dark fringe.

The four lengths are sensed with a variation of the PDH reflection scheme [25]. In standard PDH, an error signal is generated through heterodyne detection of the light reflected from a cavity. The RF phase modulation sidebands are directly reflected from the cavity input mirror and serve as a local oscillator to mix with the carrier field. The carrier experiences a phase shift in reflection, turning the RF phase modulation into RF amplitude modulation, linear in amplitude for small deviations from resonance. This concept is extended to the full interferometer as follows. At the operating point, the carrier light is resonant in the arm and recycling cavities and on a Michelson dark fringe. The RF sideband fields resonate differently. One pair of RF sidebands (from phase modulation at 62.5 MHz) is not resonant and simply reflects from the recycling mirror. The other pair (25 MHz phase modulation) is resonant in the recycling cavity but not in the arm cavities.62 The Michelson mirrors are positioned to make one arm 30 cm longer than the other so that these RF sidebands are not on a Michelson dark fringe. By design this Michelson asymmetry is chosen so that most of the resonating RF sideband power is coupled to the AS port.

In this configuration, heterodyne error signals for the four length degrees-of-freedom are extracted from the three output ports shown in figure 3 (REF, PO and AS ports). The AS port is heterodyned at the resonating RF frequency and gives an error signal proportional to differential arm length changes, including those due to a GW. The PO port is a sample of the recycling cavity beam, and is detected at the resonating RF frequency to give error signals for the recycling cavity length and the Michelson phase (using both RF quadratures). The REF port is detected at the non-resonating RF frequency and gives a standard PDH signal proportional to deviations in the laser frequency relative to the average length of the two arms. Feedback controls derived from these errors signals are applied to the two end mirrors to stabilize the differential arm length, to the beamsplitter to control the Michelson phase and to the recycling mirror to control the recycling cavity length. The feedback signals are applied directly to the mirrors through their coil–magnet actuators, with slow corrections for the differential arm length applied with longer range actuators that move the whole isolation stack.

The common arm length signal from the REF port detection is used in the final level of laser frequency stabilization [26] pictured schematically in figure 4. The hierarchical frequency control starts with the reference cavity pre-stabilization mentioned in section 4.2. The pre-stabilization path includes an acousto-optic modulator (AOM).

62 These are approximate modulation frequencies for H1 and L1; those for H2 are about 10% higher.
driven by a voltage-controlled oscillator, through which fast corrections to the pre-stabilized frequency can be made. The MC servo uses this correction path to stabilize the laser frequency to the MC length, with a servo bandwidth close to 100 kHz. The most stable frequency reference in the GW band is naturally the average length of the two arm cavities, therefore the common arm length error signal provides the final level of frequency correction. This is accomplished with feedback to the MC, directly to the MC length at low frequencies and to the error point of the MC servo at high frequencies, with an overall bandwidth of 20 kHz. The MC servo then impresses the corrections onto the laser frequency. The three cascaded frequency loops—the reference cavity pre-stabilization, the MC loop and the common arm length loop—together provide 160 dB of frequency noise reduction at 100 Hz, and achieve a frequency stability of 5 Hz rms in a 100 Hz bandwidth.

The photodetectors are all located outside the vacuum system, mounted on optical tables. Telescopes inside the vacuum reduce the beam size by a factor of ~10, and the small beams exit the vacuum through high-quality windows. To reduce noise from scattered light and beam clipping, the optical tables are housed in acoustical enclosures, and the more critical tables are mounted on passive vibration isolators. Any back-scattered light along the AS port path is further mitigated with a Faraday isolator mounted in the vacuum system.

The total AS port power is typically 200–250 mW, and is a mixture of RF sideband local oscillator power and carrier light resulting from spatially imperfect interference at the beamsplitter. The light is divided equally between four length photodetectors, keeping the power on each at a detectable level of 50–60 mW. The four length detector signals are summed and filtered, and the feedback control signal is applied differentially to the end test masses. This differential-arm servo loop has a unity-gain bandwidth of approximately 200 Hz, suppressing fluctuations in the arm lengths to a residual level of ~10−14 m rms. An additional servo is implemented on these AS port detectors to cancel signals in the RF phase orthogonal to the differential-arm channel; this servo injects RF current at each photodetector to suppress signals that would otherwise saturate the detectors. About 1% of the beam is directed to an alignment detector that controls the differential alignment of the ETMs.

Maximal power buildup in the interferometer also depends on maintaining stringent alignment levels. Sixteen alignment degrees-of-freedom—pitch and yaw for each of the six interferometer mirrors and the input beam direction—are controlled by a hierarchy of feedback loops. First, orientation motion at the pendulum and isolation stack eigenfrequencies is suppressed locally at each optic using optical lever angle sensors. Second, global alignment is established with four RF quadrant photodetectors at the three output ports as shown in figure 3. These RF alignment detectors measure wavefront misalignments between the carrier and sideband fields in a spatial version of PDH detection [27, 28]. Together the four detectors provide five linearly independent combinations of the angular deviations from optimal global alignment [29]. These error signals feed a multiple-input multiple-output control scheme to maintain the alignment within ~10−3 rad rms of the optimal point, using bandwidths between ~0.5 and ~5 Hz depending on the channel. Finally, slower servos hold the beam centered on the optics. The beam positions are sensed at the arm ends using dc quadrant detectors that receive the weak beam transmitted through the ETMs, and at the corner by imaging the beam spot scattered from the beamsplitter face with a CCD camera.

The length and alignment feedback controls are all implemented digitally, with a real-time sampling rate of 16 384 samples s⁻¹ for the length controls and 2048 samples s⁻¹ for the alignment controls. The digital control system provides the flexibility required to implement the multiple-input, multiple-output feedback controls described above. The digital controls also allow complex filter shapes to be easily realized, lend the ability to make dynamic changes in filtering and make it simple to blend sensor and control signals. As an example, optical gain changes are compensated to first order to keep the loop gains constant in time by making real-time feed-forward corrections to the digital gain based on cavity power levels.

The digital controls are also essential to implementing the interferometer lock acquisition algorithm. So far this
section has described how the interferometer is maintained at the operating point. The other function of the control system is to acquire lock: to initially stabilize the relative optical positions to establish the resonance conditions and bring them within the linear regions of the error signals. Before lock the suspended optics are only damped within their suspension structures; ground motion and the equivalent effect of input-light frequency fluctuations cause the four degrees-of-freedom simultaneously falling within the ~1 nm linear region of the resonance points is thus extremely small and a controlled approach is required. The basic approach of the lock acquisition scheme, described in detail in [30], is to control the degrees-of-freedom in sequence: first the power-recycled Michelson is controlled, then a resonance of one arm cavity is captured and finally a resonance of the other arm cavity is captured to achieve full power buildup. A key element of this scheme is the real-time, dynamic calculation of a sensor transformation matrix to form appropriate length error signals throughout the sequence. The interferometers are kept in lock typically for many hours at a time, until lock is lost due to environmental disturbances, instrument malfunction or operator command.

4.5. Thermal effects

At full power operation, a total of 20–60 mW of light is absorbed in the substrate and in the mirror surface of each ITM, depending on their specific absorption levels. Through the thermo-optic coefficient of fused silica, this creates a weak, though not insignificant thermal lens in the ITM substrates [31]. Thermo-elastic distortion of the test mass reflecting surface is not significant at these absorption levels. While the ITM thermal lens has little effect on the carrier mode, which is determined by the arm cavity radii of curvature, it does affect the RF sideband mode supported by the recycling cavity. This in turn affects the power buildup and mode shape of the RF sidebands in the recycling cavity, and consequently the sensitivity of the heterodyne detection signals [32, 33]. Achieving maximum interferometer sensitivity thus depends critically on optimizing the thermal lens and thereby the mode shape, a condition which occurs at a specific level of absorption in each ITM (approximately 50 mW). To achieve this optimum mode over the range of ITM absorption and stored power levels, each ITM thermal lens is actively controlled by directing additional heating beams, generated from CO2 lasers, onto each ITM [34]. The power and shape of the heating beams are controlled to maximize the interferometer optical gain and sensitivity. The shape can be selected to have either a Gaussian radial profile to provide more lensing, or an annular radial profile to compensate for excess lensing.

4.6. Interferometer response and calibration

The GW channel is the digital error point of the differential-arm servo loop. In principle, the GW channel could be derived from any point within this loop. The error point is chosen because the dynamic range of this signal is relatively small, since the large low-frequency fluctuations are suppressed by the feedback loop. To calibrate the error point in strain, the effect of the feedback loop is divided out, and the interferometer response to a differential arm strain is factored in [35]; this process can be done either in the frequency domain or directly in the time domain. The absolute length scale is established using the laser wavelength, by measuring the mirror drive signal required to move through an interference fringe. The calibration is tracked during operation with sine waves injected into the differential-arm loop. The uncertainty in the amplitude calibration is approximately ±10%. Timing of the GW channel is derived from the Global Positioning System; the absolute timing accuracy of each interferometer is better than ±10 µs.

The response of the interferometer output as a function of GW frequency is calculated in detail in [36–38]. In the long-wavelength approximation, where the wavelength of the GW is much longer than the size of the detector, the response $R$ of a Michelson–Fabry–Perot interferometer is approximated by a single-pole transfer function:

$$R(f) \propto \frac{1}{1 + i f / f_p},$$

where the pole frequency is related to the arm cavity storage time by $f_p = 1/4 \pi \tau_a$. Above the pole frequency ($f_p = 85$ Hz for the LIGO 4 km interferometers), the amplitude response drops off as $1/f$. As discussed below, the measurement noise above the pole frequency has a white (flat) spectrum, and so the strain sensitivity decreases proportionally to frequency in this region. The single-pole approximation is quite accurate, differing from the exact response by less than a percent up to ~1 kHz [38].

In the long-wavelength approximation, the interferometer directional response is maximal for GWs propagating orthogonally to the plane of the interferometer arms and linearly polarized along the arms. Other angles of incidence or polarizations give a reduced response, as depicted by the antenna patterns shown in figure 5. A single detector has blind spots on the sky for linearly polarized GWs.

4.7. Environmental monitors

To complete a LIGO detector, the interferometers described above are supplemented with a set of sensors to monitor the local environment. Seismometers and accelerometers measure vibrations of the ground and various interferometer components; microphones monitor acoustic noise at critical locations; magnetometers monitor fields that could couple to the test masses or electronics; radio receivers monitor RF power around the modulation frequencies. These sensors are used to detect environmental disturbances that can couple to the GW channel.

5. Instrument performance

5.1. Strain noise spectra

During the commissioning period, as the interferometer sensitivity was improved, several short science runs were
Sensing noises are phenomena that limit the ability to measure those motions; they are present even in the absence of test mass motion. The strain noises shown in figure 6 consist of spectral lines superimposed on a continuous broadband noise spectrum. The majority of the lines are due to power lines (60, 120, 180 Hz, etc), ‘violin mode’ mechanical resonances (350, 700 Hz, etc) and calibration lines (55, 400 and 1100 Hz). These high $Q$ lines are easily excluded from analysis; the broadband noise dominates the instrument sensitivity.

5.2 Sensing noise sources

Sensing noises are shown in the lower panel of figure 7. By design, the dominant noise source above 100 Hz is shot noise, as determined by the Poisson statistics of photon detection. The ideal shot-noise limited strain noise density, $\tilde{h}(f)$, for this type of interferometer is [9]

$$\tilde{h}(f) = \sqrt{\frac{\pi \lambda}{\eta P_{\text{BS}} c}} \sqrt{1 + \left(\frac{4\pi f \tau_s}{\lambda^2}ight)^2},$$

where $\lambda$ is the laser wavelength, $\tilde{h}$ is the reduced Planck constant, $c$ is the speed of light, $\tau_s$ is the arm cavity storage time, $f$ is the GW frequency, $P_{\text{BS}}$ is the power incident on the beamsplitter and $\eta$ is the photodetector quantum efficiency. For the estimated effective power of $\eta P_{\text{BS}} = 0.9 \times 250$ W, the ideal shot-noise limit is $\tilde{h} = 1.0 \times 10^{-23}$ Hz$^{-1/2}$ at 100 Hz. The shot-noise estimate in figure 7 is based on measured photocurrents in the AS port detectors and the measured interferometer response. The resulting estimate, $\tilde{h}(100 \text{Hz}) = 1.3 \times 10^{-23}$ Hz$^{-1/2}$, is higher than the ideal limit due to several inefficiencies in the heterodyne detection process: imperfect interference at the beamsplitter increases the shot noise; imperfect modal overlap between the carrier and RF sideband fields decreases the signal and the fact that the AS port power is modulated at twice the RF phase modulation frequency leads to an increase in the time-averaged shot noise [39].

Many noise contributions are estimated using stimulus-response tests, where a sine-wave or broadband noise is injected into an auxiliary channel to measure its coupling to the GW channel. This method is used for the laser frequency and amplitude noise estimates, the RF oscillator phase noise contribution and also for the angular control and auxiliary length noise terms described below. Although laser noise
Figure 7. Primary known contributors to the H1 detector noise spectrum. The upper panel shows the displacement noise components, while the lower panel shows sensing noises (note the different frequency scales). In both panels, the black curve is the measured strain noise (same spectrum as in figure 6), the dashed gray curve is the design goal and the cyan curve is the root-square-sum of all known contributors (both sensing and displacement noises). The labeled component curves are described in the text. The known noise sources explain the observed noise very well at frequencies above 150 Hz, and to within a factor of 2 in the 40–100 Hz band. Spectral peaks are identified as follows: c, calibration line; p, power line harmonic; s, suspension wire vibrational mode; m, mirror (test mass) vibrational mode.

is nominally common-mode, it couples to the GW channel through small, unavoidable differences in the arm cavity mirrors [40, 41]. Frequency noise is expected to couple most strongly through a difference in the resonant reflectivity of the two arms. This causes carrier light to leak out the AS port, which interferes with frequency noise on the RF sidebands to create a noise signal. The stimulus-response measurements indicate that the coupling is due to a resonant reflectivity difference of about 0.5%, arising from a loss difference of tens of ppm between the arms. Laser amplitude noise can couple through an offset from the carrier dark fringe. The measured coupling is linear, indicating an effective static offset of ~1 pm, believed to be due to mode shape differences between the arms.

5.3 Seismic and thermal noise
Displacement noises are shown in the upper panel of figure 7. At the lowest frequencies the largest such noise is seismic
noise—motions of the earth’s surface driven by wind, ocean waves, human activity and low-level earthquakes—filtered by the isolation stacks and pendulums. The seismic contribution is estimated using accelerometers to measure the vibration at the isolation stack support points, and propagating this motion to the test masses using modeled transfer functions of the stack and pendulum. The seismic wall frequency, below which seismic noise dominates, is approximately 45 Hz, a bit higher than the goal of 40 Hz, as the actual environmental vibrations around these frequencies are ~10 times higher than what was estimated in the design.

Mechanical thermal noise is a more fundamental effect, arising from finite losses present in all mechanical systems, and is governed by the fluctuation-dissipation theorem [42, 43]. It causes arm length noise through thermal excitation of the test mass pendulums (suspension thermal noise) [44], and thermal acoustic waves that perturb the test mass mirror surface (test mass thermal noise) [45]. Most of the thermal energy is concentrated at the resonant frequencies, which are designed (as much as possible) to be outside the detection band. Away from the resonances, the level of thermal noise is proportional to the mechanical dissipation associated with the wire radius to the fourth power, it helps to make the wire as thin as possible to limit thermal noise. The pendulums are designed (as much as possible) to be outside the detection band. Away from the resonances, the level of thermal motion is proportional to the mechanical dissipation associated with the motion. Designing the mirror and its pendulum to have very low mechanical dissipation reduces the detection-band thermal noise. It is difficult, however, to accurately and unambiguously establish the level of broadband thermal noise in situ; instead, the thermal noise curves in figure 7 are calculated from models of the suspension and test masses, with mechanical loss parameters taken from independent characterizations of the materials.

For the pendulum mode, the mechanical dissipation occurs near the ends of the suspension wire, where the wire flexes. Since the elastic energy in the flexing regions depends on the wire radius to the fourth power, it helps to make the wire as thin as possible to limit thermal noise. The pendulums are thus made with steel wire for its strength; with a diameter of 300 µm the wires are loaded to 30% of their breaking stress. The thermal noise in the pendulum mode of the test masses is estimated assuming a frequency-independent mechanical loss angle in the suspension wire of $3 \times 10^{-4}$ [46]. This is a relatively small loss for a metal wire [47].

Thermal noise of the test mass surface is associated with mechanical damping within the test mass. The fused-silica test mass substrate material has very low mechanical loss, of order $10^{-7}$ or smaller [48]. On the other hand, the thin-film, dielectric coatings that provide the required optical reflectivity—alternating layers of silicon dioxide and tantalum pentoxide—have relatively high mechanical loss. Even though the coatings are only a few micrometers thick, they are the dominant source of the relevant mechanical loss, due to their level of dissipation and the fact that it is concentrated on the test mass face probed by the laser beam [43]. The test mass thermal noise estimate is calculated by modeling the coatings as having a frequency-independent mechanical dissipation of $4 \times 10^{-4}$ [45].

5.4. Auxiliary degree-of-freedom noise

The auxiliary length noise term refers to noise in the Michelson and power recycling cavity servo loops which couple to the GW channel. The former couples directly to the GW channel while the latter couples in a manner similar to frequency noise. Above ~50 Hz the sensing noise in these loops is dominated by shot noise; since loop bandwidths of ~100 Hz are needed to adequately stabilize these degrees-of-freedom, shot noise is effectively added onto their motion. Their noise infiltration to the GW channel, however, is mitigated by appropriately filtering and scaling their digital control signals and adding them to the differential-arm control signal as a type of feedforward noise suppression [24]. These correction paths reduce the coupling to the GW channel by 10–40 dB.

We illustrate this more concretely with the Michelson loop. The shot-noise-limited sensitivity for the Michelson is $\sim 10^{-16} \text{m Hz}^{-1/2}$. Around 100 Hz, the Michelson servo impresses this sensing noise onto the Michelson degree-of-freedom (specifically, onto the beamsplitter). Displacement noise in the Michelson couples to displacement noise in the GW channel by a factor of $\pi/(\sqrt{2}F) = 1/100$, where $F$ is the arm cavity finesse. The Michelson sensing noise would thus produce $\sim 10^{-18} \text{m Hz}^{-1/2}$ of GW channel noise around 100 Hz, if uncorrected. The digital correction path subtracts the Michelson noise from the GW channel with an efficiency of 95% or more. This brings the Michelson noise component down to $\sim 10^{-20} \text{m Hz}^{-1/2}$ in the GW channel, 5–10 times below the GW channel noise floor.

Angular control noise arises from noise in the alignment sensors (both optical levers and wavefront sensors), propagating to the test masses through the alignment control servos. Though these feedback signals affect primarily the test mass orientation, there is always some coupling to the GW degree-of-freedom because the laser beam is not perfectly aligned to the center-of-rotation of the test mass surface [49]. Angular control noise is minimized by a combination of filtering and parameter tuning. Angle control bandwidths are 10 Hz or less and strong low-pass filtering is applied in the GW band. In addition, the angular coupling to the GW channel is minimized by tuning the center-of-rotation, using the four actuators on each optic, down to typical residual coupling levels of $10^{-3}–10^{-4} \text{m rad}^{-1}$.

5.5. Actuation noise

The actuator noise term includes the electronics that produce the coil currents keeping the interferometer locked and aligned, starting with the digital-to-analog converters (DACs). The actuation electronics chain has extremely demanding dynamic range requirements. At low frequencies, control currents of ~10 mA are required to provide ~5 µm of position control, and tens of milliamperes are required to provide ~0.5 mrad of alignment bias. Yet the current noise through the coils must be kept below a couple of pA/√Hz above 40 Hz. The relatively limited dynamic range of the DACs is managed with a combination of digital and analog filtering; the higher frequency components of the control signals are digitally emphasized before being sent to the DACs, and
then de-emphasized following the DACs with complementary analog filters. The dominant coil current noise comes instead from the circuits that provide the alignment bias currents, followed closely by the circuits that provide the length feedback currents.

5.6. Additional noise sources

In the 50–100 Hz band, the known noise sources typically do not fully explain the measured noise. Additional noise mechanisms have been identified, though not quantitatively established. Two potentially significant candidates are non-linear conversion of low-frequency actuator coil currents to broadband noise (upconversion) and electric charge buildup on the test masses. A variety of experiments have shown that the upconversion occurs in the magnets (neodymium iron boron) of the coil-magnet actuators, and produces a broadband force noise, with a $f^{-2}$ spectral slope; this is the phenomenon known as Barkhausen noise [50]. The non-linearity is small but not negligible given the dynamic range involved: 0.1 mN of low-frequency (below a few hertz) actuator force upconverts of order $10^{-13}$ N rms of force noise in the 40–80 Hz octave. This noise mechanism is significant primarily below 80 Hz, and varies in amplitude with the level of ground motion at the observatories.

Regarding electric charge, mechanical contact of a test mass with its nearby limit-stops, as happens during a large earthquake, can build up charge between the two objects. Such charge distributions are not stationary; they tend to redistribute on the surface to reduce local charge density. This produces a fluctuating force on the test mass, with an expected $f^{-1}$ spectral slope. Although the level at which this mechanism occurs in the interferometers is not well known, evidence for its potential significance comes from a fortuitous event with L1. Following a vacuum vent and pump-out cycle partway through the S5 science run, the strain noise in the 50–100 Hz band went down by about 20%; this was attributed to charge reduction on one of the test masses.

In addition to these broadband noises, there are a variety of periodic or quasi-periodic processes that produce lines or narrow features in the spectrum. The largest of these spectral peaks are identified in figure 7. The groups of lines around 350 Hz, 700 Hz, etc are vibrational modes of the wires that suspend the test masses, thermally excited with $kT$ of energy in each mode. The power line harmonics, at 60 Hz, 120 Hz, 180 Hz, etc infiltrate the interferometer in a variety of ways. The 60 Hz line, for example, is primarily due to the power line’s magnetic field coupling directly to the test mass magnets. As all these lines are narrow and fairly stable in frequency, they occupy only a small fraction of the instrument spectral bandwidth.

5.7. Other performance figures-of-merit

While figures 6 and 7 show high-sensitivity strain noise spectra, the interferometers exhibit both long- and short-term variation in sensitivity due to improvements made to the detectors, seasonal and daily variations in the environment, and the like. One indicator of the sensitivity variation over the S5 science run is shown in figure 8: histograms of the rms strain noise in the frequency band of 100–200 Hz.

To get a sense of shorter term variations in the noise, figure 9 shows the distribution of strain noise amplitudes at three representative frequencies where the noise is dominated by random processes. For stationary, Gaussian noise the amplitudes would follow a Rayleigh distribution, and deviations from that indicate non-Gaussian fluctuations. As figure 9 suggests, the lower frequency end of the measurement band shows a higher level of non-Gaussian noise than the higher frequencies. Some of this non-Gaussianity is due to known couplings to a fluctuating environment; much of it, however, is due to glitches—any short duration noise transient—from unknown mechanisms. Additional characterizations of the glitch behavior of the detectors can be found in [51].

Another important statistical figure-of-merit is the interferometer duty cycle, the fraction of time that detectors are operating and taking science data. Over the S5 period, the individual interferometer duty cycles were 78%, 79% and 67% for H1, H2 and L1, respectively; for double coincidence between L1 and H1 or H2 the duty cycle was 60%; and for triple coincidence of all three interferometers the duty cycle was 54%. These figures include scheduled maintenance and instrument tuning periods, as well as unintended losses of operation.

6. Data analysis infrastructure

While the LIGO interferometers provide extremely sensitive measurements of the strain at two distant locations, the
measure detection efficiencies. These injections are done both in software, where the waveforms are added to the archived data stream, and directly in hardware, where they are added to the feedback control signal in the differential-arm servo. In general, the injected waveforms simulate the actual signals being searched for, with representative waveforms used to test searches for unknown signals.

As described in the section on instrument performance, the local environment and the myriad interferometer degrees-of-freedom can all couple to the GW channel, potentially creating artifacts that must be distinguished from actual signals. Instrument-based vetoes are developed and used to reject such artifacts [51]. The vetoes are tested using hardware injections to ensure their safety for GW detections. The efficacy of these vetoes depends on the search type.

7. Astrophysical reach and search results

LIGO was designed so that its data could be searched for GWs from many different sources. The sources can be broadly characterized as either transient or continuous in nature, and for each type, the analysis techniques depend on whether the gravitational waveforms can be accurately modeled or whether only less specific spectral characterizations are possible. We therefore organize the searches into four categories according to source type and analysis technique.

(i) Transient, modeled waveforms: the compact binary coalescence search. The name follows from the fact that the best understood transient sources are the final stages of binary inspirals [52], where each component of the binary may be a NS or a BH. For these sources the waveform can be calculated with good precision, and matched-filter analysis can be used.

(ii) Transient, unmodeled waveforms: the gravitational-wave bursts search. Transient systems, such as core-collapse supernovae [53], BH mergers and NS quakes, may produce GW bursts that can only be modeled imperfectly, if at all, and more general analysis techniques are needed.

(iii) Continuous, narrow-band waveforms: the continuous wave sources search. An example of a continuous source of GWs with a well-modeled waveform is a spinning NS (e.g. a pulsar) that is not perfectly symmetric about its rotation axis [54].

(iv) Continuous, broadband waveforms: the stochastic gravitational-wave background search. Processes operating in the early universe, for example, could have produced a background of GWs that is continuous but stochastic in character [55].

In the following sections we review the astrophysical results that have been generated in each of these search categories using LIGO data; [56] contains links to all the LIGO observational publications. To date, no GW signal detections have been made, so these results are all upper limits on various GW sources. In those cases where the S5 analysis is not yet complete, we present the most recent published results and also discuss the expected sensitivity, or astrophysical reach, of the search based on the S5 detector performance.
7.1. Compact binary coalescences

Binary coalescences are unique laboratories for testing general relativity in the strong-field regime [57]. GWs from such systems will provide unambiguous evidence for the existence of BHs and powerful tests of their properties as predicted by general relativity [58, 59]. Multiple observations will yield valuable information about the population of such systems in the universe, up to distances of hundreds of megaparsecs (Mpc, 1 parsec = 3.3 light years). Coalescences involving NSs will provide information about the nuclear equation of state in these extreme conditions. Such systems are considered likely progenitors of short-duration gamma-ray bursts (GRBs) [60].

Post-Newtonian approximations to general relativity accurately model a binary system of compact objects whose orbit is adiabatically tightening due to GW emission [61]. Several examples of such binary systems exist with merger times less than the age of the universe, most notably the binary pulsar system PSR 1913 + 16 described previously. After an extended inspiral phase, the system becomes dynamically unstable when the separation decreases below an innermost stable circular orbit (approximately 25 km for two solar-mass NSs) and the objects plunge and form a single BH in the merger phase. The resulting distorted BH relaxes to a stationary Kerr state via the strongly damped sinusoidal oscillations of the quasi-normal modes in the ringdown phase. The smoothly evolving inspiral and ringdown GW waveforms can be approximated analytically, while the extreme dynamics of the merger phase require numeric solutions to determine the GW waveform [62]. Collectively, the inspiral, merger and ringdown of a binary system is termed a compact binary coalescence (CBC).

The waveform for a compact binary inspiral is a chirp: a sinusoid increasing in frequency and amplitude until the end of the inspiral phase. The inspiral phase of a binary neutron star (BNS, with each mass assumed to be 1.4 \( m_\odot \)) will complete nearly 2000 orbits in the LIGO band over tens of seconds before merger, and emit a maximum GW frequency of about 1500 Hz. Higher mass inspirals terminate at proportionally lower GW frequencies. For non-spinning objects, the inspiral waveform is uniquely determined by the two component masses \( m_1 \) and \( m_2 \) of the system [63]. No analytic waveforms exist for the merger phase; calculating these waveforms is one of the primary goals of numerical relativity [64, 65]. The ringdown phase is described by an exponentially damped sinusoid, determined by the quasi-normal mode frequency and the quality factor of the final BH [66].

7.1.1. Analysis method. Since the inspiral and ringdown waveforms for a given mass pair \((m_1, m_2)\) are accurately known, searches for them are performed using optimal matched filtering employing a bank of templates covering the desired \((m_1, m_2)\) parameter space. An optimized algorithm generates the template bank, minimizing the number of templates while allowing a maximum signal-to-noise ratio (SNR) loss of 3% [67–69]. In practice approximately 7000 templates are used to cover total masses between \( 2M_\odot \) and \( 35M_\odot \).

The matched filtering process generates a trigger when the SNR of the filter output exceeds a threshold. The threshold is set by balancing two factors: it must be low enough so that a good estimation can be made of the background due to detector noise, and it must be high enough to keep the number of triggers manageable. Associated with each trigger is a specific template, or mass pair, and a coalescence time which maximize the SNR for that signal event [70].

Triggers are first generated independently for each detector. The number of false triggers created by detector noise is then greatly reduced by finding the set of coincident triggers—those that correspond to similar template masses and coalescence times, within appropriate windows, between at least two LIGO detectors. Coincident triggers are subject to additional consistency checks, such as the \( \chi^2 \) [71] and \( r^2 \) [72] tests.

Typically many thousands of coincident triggers per month remain at the end of the pipeline. These surviving triggers are compared with the background from accidental coincidences of triggers due to detector noise. Time shift trials are used to estimate the background: the analysis is repeated with the triggers from different detectors shifted in time relative to each other by an amount large compared with the coincidence window. A hundred such trials are typically made. For each region of mass parameter space, the time shift trials establish a false alarm rate as a function of SNR. In-time coincident triggers with the smallest false alarm rate are potential detection candidates [73].

A large number of software injections is made to tune the analysis pipeline and evaluate its detection efficiency. The injected waveforms cover the largest practical range of parameter space possible (component masses, spins, orientations, sky locations and distances). The resulting detection efficiency is combined with simple models of the astrophysical source distribution to arrive at an estimated cumulative luminosity to which the search is sensitive. These models [74, 75] predict that the rate of CBCs should be proportional to the stellar birth rate in nearby spiral galaxies. This birth rate can be estimated from a galaxy’s blue luminosity\(^{63} \), so we express the cumulative luminosity in units of \( L_{10} \), where \( L_{10} \) is \( 10^{40} \) times the blue solar luminosity (the Milky Way contains \( \sim 1.7L_{10} \)).

7.1.2. Analysis results. To date, the detection candidates resulting from the analysis pipeline are consistent with the estimated background and thus are likely accidental coincidences. In the absence of detection, mass-dependent upper limits are set on the rate of CBCs in the local universe. These rate limits are expressed per unit \( L_{10} \).

An inspiral search with total masses between \( 2M_\odot \) and \( 35M_\odot \) has been completed using the first calendar year of S5 data [73]. Figure 10 shows the resulting rate upper limit for low-mass binary coalescences as a function of the total mass (left), and as a function of the mass of a BH in a BH–NS system with a NS mass of \( 1.35M_\odot \) (right). The same analysis set a BNS coalescence rate upper limit of \( 3.8 \times 10^{-2} \text{yr}^{-1} L_{10}^{-1} \).

\(^{63}\) Blue luminosity is short for B-band luminosity, signifying one of a standard set of optical filters used in measuring the luminosity of galaxies.
Figure 10. S5 year 1 upper limits on the binary coalescence rate per year and per L10 as a function of total mass of the binary system assuming a uniform distribution in the mass ratio (left) and as a function of the mass of a BH in a BH–NS system with a NS mass of 1.35$M_\odot$ (right). The darker area shows the excluded region when accounting for marginalization over systematic errors. The lighter area shows the additional region that would have been excluded if systematic errors had been ignored. Reprinted figure with permission from B P Abbott et al 2009 Phys. Rev. D 79 122001 [73]. Copyright (2009) by the American Physical Society.

This upper limit is still significantly higher than recent CBC rate estimates derived from the observed BNS population—approximately $5 \times 10^{-5}$ yr$^{-1}L_{10}^{-1}$ for NS/NS binaries [75].

Since the LIGO sensitivities improved as S5 progressed, analysis of the full data set should provide significantly more interesting coalescence results. In the meantime, the astrophysical reach for these sources can be estimated from the detector noise performance. The minute-by-minute strain noise spectra for each detector are used to calculate the horizon distance: the maximum distance at which an inspiral could be detected with an SNR of 8. For BNS inspirals, the horizon distance was 30–35 Mpc each for L1 and H1 and about 17 Mpc for H2. Based on the increased horizon distances and extrapolations from the first-year search results, we expect to achieve better than a factor of 2 increase in cumulative exposure with the full run analysis.

The sensitivity to BH ringdowns is similarly estimated using the S5 detector strain noise. Figure 11 shows the single detector range for BH ringdowns averaged over sky position and spin orientation. The range estimate assumes 1% of total mass is radiated as GWs, in rough agreement with numerical simulations. Unlike NS inspirals, the abundance of such ‘intermediate mass BHs’ and hence their merger rate is difficult to predict [62].

Searches are also in progress for GWs from CBCs with total masses up to 100 solar masses, and from CBCs coincident with short-hard GRBs observed during the S5 run. In addition, procedures are being developed for establishing confidence in candidate detection events and for extracting the physical parameters of detected events.

7.2. GW bursts

In addition to the well-modeled signals described in previous sections, we search for GW ‘bursts’, defined as any short-duration signal ($t \lesssim 1$ s) with significant signal power in the detectors’ sensitive frequency band (45 $\leq f \leq 2000$ Hz). For example, the collapsing core of a massive star (the engine that powers a type II supernova) can emit GWs through a number of different mechanisms [76]. A compact binary merger—discussed in the earlier section about CBC searches—may be considered a burst, especially if the mass is large so that the bulk of the long inspiral signal is below the sensitive frequency band of the detectors, leaving only a short signal from the actual merger to be detected. Cosmic strings, if they exist, are generically expected to bend into cusps and kinks which are efficient radiators of beamed GWs. There may well be other astrophysical sources, since any energetic event that involves an asymmetric reshaping or re-orientation of a significant amount of mass will generate GWs.

Many energetic gravitational events will also emit electromagnetic radiation and/or energetic particles that can be observed with telescopes and other astronomical instruments, as in the case of supernovae. Thus, besides searching for GW
signals alone, we can search for a class of joint emitters and use information from conventional observations to constrain the GW event time and sky position, allowing a more sensitive ‘externally triggered’ search. For example, GRBs and soft gamma-ray repeater (SGR) flares are highly energetic events that make excellent targets for externally triggered GW burst searches. While the progenitor(s) of GRBs are not entirely clear, most if not all short-duration GRBs are thought to be produced by mergers of NSs or of a NS with a BH, which would radiate a great deal of energy in GWs. Similarly, SGRs are believed to be NSs with very high magnetic fields (i.e. magnetars) that sporadically produce flares of electromagnetic radiation. The flares may be related to deformations of the NS crust which could couple to GW emission. If an associated GW signal for these progenitors is detected, the combined GW and EM/particle data will reveal complementary information about the astrophysics of the event.

### 7.2.1. Analysis methods.

A number of robust burst detection methods have been developed that do not rely on knowledge of the signal waveform. Most fit into one of three general categories: excess power, cross-correlation or coherent.

**Excess power** methods decompose the data into different frequency components, either with a Fourier basis or with some family of wavelets, and look for signal power that is significantly above the baseline detector noise level in some time–frequency region. An excess power method typically generates triggers from each detector, and then applies a coincidence test to find consistent event candidates with excess power in two or more detectors.

**Cross-correlation** methods directly compare the data streams from a pair of detectors to look for a common signal within uncorrelated noise. A cross-correlation statistic is calculated by integrating over a short time window—ideally, comparable in length to the duration of the signal—with a range of relative time delays corresponding to different GW arrival directions. The cross-correlation is insensitive to the relative amplitude of the common signal in the two data streams which may be different due to the antenna response of the detectors.

**Coherent** methods generalize the concepts of excess power and cross-correlation to take full advantage of having three or more data streams. Detectors at each site see a different linear combination of the same two time-dependent GW polarization components, so a network of detectors at three sites (e.g. the two LIGO sites plus Virgo) has enough information to determine the waveform and provide a consistency test for each hypothetical arrival direction. This is essentially a maximum likelihood approach on the space of possible GW signals, except that a ‘regulator’ or Bayesian prior is used to disfavor physically unlikely scenarios [77, 78]. If only two sites are available, the use of this regulator allows a somewhat weaker coherent analysis to be performed on data from only two detectors. In externally triggered searches, coherent analysis is simpler because the sky location of the potential signal is already known. In this case two sites are sufficient to fully determine the GW signal.

Each of these analysis methods produces a statistic (or more than one) that describes the ‘strength’ of the event candidate. The strength statistics are compared with the background distribution using time shift analysis, like the CBC searches. Externally triggered searches also determine the background from time shifted off-source data.

These search methods generally work well for a wide range of signals, with some waveform-dependent variation between methods. They are less sensitive than matched filtering for a known signal but are computationally efficient and are often within a factor of 2 in sensitivity.

### 7.2.2. Analysis results: all-sky burst searches.

The most general searches are those that look for GW bursts coming from any sky position at any time. Because there is no morphological distinction between a GW burst signal and an instrumental glitch, these ‘all-sky’ searches place stringent demands on data quality evaluation, instrumental veto conditions and consistency tests among detectors. The primary S4 all-sky burst search [79] was designed to detect signals with frequency content in the range $64$–$1600$ Hz and durations of up to $\sim 1$ s. It identified event candidates with an analysis pipeline consisting of two stages. First, a wavelet-based excess power method was used to find instances of coincident excess power in all three detectors. Second, candidate triggers were generated with highly significant correlation compared with background as well as positive definite correlation and strain amplitude between the two Hanford detectors. No significant event candidates were identified in 15.53 days of observation; based on this, we placed an upper limit at 90% confidence on the rate of detectable GW bursts of 0.15 per day.

To interpret a null result such as this one, a Monte Carlo method evaluates what signals could have been detected by the search. The data are re-processed with simulated GW signals using the same analysis pipeline to measure the detection efficiency in the presence of actual detector noise. The intrinsic amplitude of a simulated burst signal is characterized by a model-independent quantity, the ‘root-sum-square’ GW strain, $h_{rss}$, that expresses the amplitude of the GW signal arriving at the Earth without regard to the response of any particular detector. It has units of Hz$^{-1/2}$, allowing it to be directly related to the amplitude spectral density of the detector noise as shown in figure 12.

In principle, the efficiency of a burst search pipeline can be evaluated for any modeled GW waveform, e.g. from a core collapse simulation or a binary merger signal generated using numerical relativity. In practice, the search efficiency is evaluated for a collection of ad hoc waveforms that have certain general features but do not correspond to any particular physical model. One of our standard waveforms is a ‘sine-Gaussian’, a sinusoidal signal with central frequency $f$ within a Gaussian envelope with dimensionless width parameter $Q$.

Evaluating the detection efficiency as a function of frequency, figure 12 shows the effective rate limit as a function of signal strength using an ‘exclusion diagram’.

To understand the reach of the analysis in astrophysical terms, the search sensitivity in terms of $h_{rss}$ can be related to a corresponding energy emitted in GWs, $E_{GW}$. As discussed in the S4 all-sky burst search paper [79], for sine-Gaussians and
other quasi-periodic signals,

\[ E_{GW} \sim \frac{r^2 \nu^3}{4G} (2\pi f)^2 h_{ns}^2. \]  

(3)

where the GW energy emission is assumed to be isotropic. GW emission is not isotropic, but the energy flux varies by a factor of no more than 4. Using the fact that the S5 data has lower noise than S4 by approximately a factor of 2, sources at a typical Galactic distance of 10 kpc could be detected for energy emission in GWs as low as \(5 \times 10^{-8} M_\odot\). For a source in the Virgo galaxy cluster, approximately 16 Mpc away, GW energy emission as low as \(\sim 0.12 M_\odot\) could be detected.

We can draw more specific conclusions about detectability for models of astrophysical sources that predict the absolute energy and waveform emitted. Following the discussion in [79], we estimate that a similar burst search using S5 data could detect the core-collapse signals modeled by Ott et al. [80] out to 0.4 kpc for their 11M_\odot non-spinning progenitor (model s11WW) and to 16 kpc for their 15M_\odot spinning progenitor (model m15b6). The latter of these would be detectable throughout most of our Galaxy. A merger of two 10M_\odot BHs would be detectable out to a distance of approximately 3 Mpc, while a merger of two 50M_\odot BHs could be detected as far away as \(\sim 120\) Mpc.

7.2.3. Analysis results: externally triggered burst searches. The exceptionally intense GRB 070201 was a particularly interesting event for a triggered burst search because the sky position, determined from the gamma-ray data, overlapped one of the spiral arms of the large, nearby galaxy M31 (Andromeda). An analysis of GW data [81] found no evidence of an inspiral or a more general burst signal; that finding ruled out (at the \(\sim 99\%\) level) the possibility of a binary merger in M31 being the origin of GRB 070201.

We have searched for GW bursts associated with the giant flare of SGR 1806 – 20 that occurred on 27 December 2004 (between the S4 and S5 runs, but at a time when the LIGO H1 detector was operating, albeit with reduced sensitivity) plus 190 smaller flares of SGRs 1806 – 20 and 1900 + 14 during the S5 run [82]. No GW signals were identified. Energy emission limits were established for a variety of hypothetical waveforms, many of them within the energy range allowed by some models and some as low as \(3 \times 10^{38}\) J. Future observations—especially for giant flares and flares of the recently discovered SGR 0501+4516 which is closer to Earth—will be sensitive to GW energy emission at or below the level of observed electromagnetic energies.

Externally triggered GW burst searches are in progress or planned using observations of supernovae, anomalous optical transients, radio bursts and neutrinos as triggers. In general, the constraints on event time, sky position and (possibly) signal properties provided by the external triggers make these searches a few times more sensitive in amplitude than all-sky searches. It is thus possible to investigate a rich population of energetic transient events that may plausibly produce detectable GWs.

7.3. Continuous wave sources

Continuous GW signals may be generated by rotating NSs such as those powering millisecond radio pulsars. In these systems, a quadrupole mass asymmetry, or ellipticity, \(\epsilon\), radiates GWs at twice the NS rotation frequency. The maximum sustainable ellipticity, and hence the maximum GW emission, is a function of the NSs internal structure and equation of state. Current limits on the ellipticity are based on the change in frequency of the radio pulsar signal, the spin-down rate, assuming that the spin-down is entirely due to GW emission. An especially interesting candidate is the Crab pulsar, for which the spin-down bound on ellipticity is \(\epsilon \lesssim 7.2 \times 10^{-4}\) and for which the bound on detectable strain is \(h \lesssim 1.4 \times 10^{-24}\) at about 59.6 Hz, twice its spin frequency [83]. 'Standard' NS equations of state predict \(\epsilon \lesssim 10^{-7}\), while exotic pulsars such as quark stars may have \(\epsilon \lesssim 10^{-4}\) [84]. For most radio pulsars, however, the spin-down limit overestimates the ellipticity and associated GW emission because of electromagnetic damping of the rotation.

Compared with CBCs or bursts, NS powered millisecond radio pulsars are a weak source of GWs which LIGO can detect only if the source is within a few hundred parsecs. Nonetheless, there are dozens of known sources within this range that may be detected if they have sufficiently high ellipticity. Furthermore, millisecond pulsars are attractive sources of continuous GWs since the stable rotation periods allow coherent integration over many hours, weeks and months to improve the SNR.

7.3.1. Analysis methods. The detectable waveform from a rotating NS is a function of at least six source parameters: two each for the pulsar position and orientation on the sky and at least two for the spin frequency and frequency drift (1st time derivative). The intrinsic phase of a spinning NS waveform, \(\phi(T)\), is modeled as an approximate sinusoid at instantaneous frequency \(\nu\) and spin-down rate \(\dot{\nu}\). The observed phase in the detector frame, \(\phi(t)\), is in general a more complicated function of time due to the variable time delay \(\delta t = T - t\). The delay \(\delta t\) contains components arising from the Earth's orbital motion.
(for which $|\delta t| \leq 8.5 \text{ min}$), from the Earth’s sidereal motion ($|\delta t| \leq 43 \mu s$) and from the general relativistic Shapiro delay ($|\delta t| \leq 120 \mu s$) for signals passing close to the sun [85].

The six-dimensional parameter space and long duration of the S5 run makes all-sky coherent searches for unknown NSs, for which the amplitude and phase variations are tracked throughout the observation time, computationally prohibitive. Three techniques that trade off between sensitivity and computation have been implemented: (1) semi-coherent, long duration all-sky searches sensitive only to power and neglecting phase using the entire data set [86]; (2) coherent, short-duration all-sky searches sensitive to amplitude and phase but computationally limited to $\approx 5000 \text{ h}$ integration time [87]; (3) coherent, targeted searches for millisecond radio pulsars with accurate and stable ephemerides using the entire data set [88]. Although the coherent targeted search is the most sensitive, only a little more than 100 known radio pulsars have suitable ephemerides, while NS formation rates predict that many hundred millisecond pulsars should exist within a detectable volume [89]. Thus even though the all-sky searches are not as sensitive as the targeted search, they are worth performing.

The LIGO Scientific Collaboration has implemented several different incoherent all-sky searches. The most recent results using the S5 data are from PowerFlux [89]. The search averages strain power from short Fourier transforms (SFTs) over the full run to look for excess power in a narrow frequency bin. The SFTs are calculated using contiguous 30 min data segments. Before summing, each SFT is shifted by a sky position-dependent factor to account for the time delays discussed above, and weighted according to the detector antenna response and average noise power. Frequency bins with high SNR are checked for coincidence between multiple detectors and followed up with coherent searches.

An alternative all-sky search using longer coherence times (>1 day) offers improved sensitivity, but its computational demands require a new paradigm: distributed computing using the Einstein@Home network [90]. Einstein@Home users volunteer their idle computing CPU cycles to perform a coherent analysis. The combined resources of 50 000 volunteers with 100 000 CPUs enables an all-sky search for rotating NSs in 5280 h of the most sensitive S5 data. The Einstein@Home search is based on the coherent $\mathcal{F}$-statistic in the frequency domain [54]. Each CPU in the distributed network calculates the coherent signal for each frequency bin and sky position for a 30 h contiguous segment. The loudest frequency bins are followed up with coincidence studies between detectors and continuity studies with adjacent time segments.

The deepest searches are performed for millisecond radio pulsars with well-characterized, stable ephemerides. The 154 pulsars with spin frequencies greater than 25 Hz are selected from the Australian Telescope National Facility online catalogue [91]. Of these, 78 have sufficient stability and timing resolution to make knowledge of their waveform capable of improving the detection SNR over the long observation time. To consistently incorporate the prior information, the targeted search uses a time-domain, Bayesian analysis in which the detection likelihood is calculated for each detector. Information from multiple detectors is combined to form a joint likelihood assuming the detectors’ noises are independent. This procedure allows upper limits from successive science runs to be combined and provides a natural framework for incorporating uncertainties in the ephemerides.

7.3.2. Analysis results. Analyses of the full S5 data are underway using the techniques described above. An all-sky search using the PowerFlux technique on the first 8 months of S5 with the H1 and L1 detectors has been completed [89]. This produced upper limits on strain amplitude in the band 50–1100 Hz. For a NS with equatorial ellipticity of $10^{-6}$, the search was sensitive to distances as great as 500 pc.

Because of the narrow bandwidth (10$^{-6}$ Hz) and complicated frequency modulation of pulsar signals, instrument artifacts do not significantly contribute to the noise in pulsar searches. The few exceptions—non-stationary noise near 60 Hz harmonics, wandering lines, etc.—have been easy to identify and remove. Consequently, we can predict the astrophysical reach of the full S5 data set with a high degree of confidence based on the performance of previous searches and the S5 noise performance. Figure 13 shows the projected S5 strain amplitude sensitivity for the more sensitive searches, along with the upper limits established by the PowerFlux analysis.

7.4. Stochastic GW background

A stochastic background of GWs could result from the random superposition of an extremely large number of unresolved and

Figure 13. Limits on GW strain from rotating NSs. Upper curve (black points): all-sky strain upper limits on unknown NSs for spin-down rates as high as $5 \times 10^{-9} \text{ Hz s}^{-1}$ and optimal orientation, from analysis of the first 8 months of S5 data [89]. Middle curve (gray points): expected sensitivity for the Einstein@Home search with 5280 h of S5 data. Lower curve (gray band): expected range for 95% confidence level Bayesian upper limits on radio pulsars with known ephemerides, using the full S5 data. Black triangles: upper limits on GW emission from known radio pulsars based on their observed spin-down rates.
independent GW emission events [92]. Such a background is analogous to the cosmic microwave background radiation, though its spectrum is unlikely to be thermal. The emission events could be the result of cosmological phenomena, such as the amplification of vacuum fluctuations during inflation or in pre-big-bang models; phase transitions in the history of the universe or cosmic strings, topological defects that may have been formed during symmetry-breaking phase transitions in the early universe. Or a detectable background could result from many unresolved astrophysical sources, such as rotating NSs, supernovae or low-mass x-ray binaries.

Theoretical models of such sources are distinguished by the power spectra they predict for the stochastic background production. The spectrum is usually described by the dimensionless quantity \( \Omega_{GW}(f) \), which is the GW energy density per unit logarithmic frequency, divided by the critical energy density \( \rho_c \) to close the universe:

\[
\Omega_{GW}(f) = \frac{\int \frac{d\rho_{GW}}{\rho_c} \frac{df}{f}}{\rho_c}.
\]  

(4)

In the LIGO frequency band, most of the model spectra are well approximated by a power-law: \( \Omega_{GW}(f) \propto f^\alpha \). LIGO analyses consider a range of values for \( \alpha \), though in this review we focus on results for a frequency independent \( \Omega_{GW}(\alpha = 0) \), since many of the cosmological models predict a flat or nearly flat spectrum over the LIGO band. The strain noise power spectrum for a flat \( \Omega_{GW} \) falls as \( f^{-3} \), with a strain amplitude scale of\(^{64}\):

\[
h_{GW} = 4 \times 10^{-22} \sqrt{\Omega_{GW}} \left( \frac{100 \text{ Hz}}{f} \right)^{3/2} \text{Hz}^{-1/2}.
\]  

(5)

7.4.1. Analysis method. Unlike the cosmic microwave background, any GW stochastic background will be well below the noise floor of a single detector. To probe below this level, we cross-correlate the output of two detectors [93]. Assuming the detector noises are independent of each other, the cross-correlation measurement will only use the square root of the total noise power spectrum due to a background \( \Omega_{GW} \) present in each detector. Therefore, any increase in the product of the integration time \( T \) and the effective bandwidth \( (\Delta f) \) of the correlation and the noise as \( (\Delta f)^{1/2} \). Thus with a sufficiently long observation time and wide bandwidth, a small background signal can, in principle, be detected beneath the detector noise floor.

The assumption of independent detector noise is crucial, and it is valid when comparing L1 with either of the Hanford detectors due to their wide physical separation. But this separation also extracts a price: the coherent cross-correlation of a stochastic background signal is reduced by the separation time delay between the detectors and the non-parallel alignment of their arms. These effects are accounted for by the overlap reduction function \( \gamma(f) \), which is unity for co-located and co-aligned detectors, and decreases below unity when they are shifted apart or mis-aligned. For a Livingston–Hanford detector pair, the overlap is on average \( \langle \gamma \rangle \sim 0.1 \) in the sensitive band around 100 Hz.

The low-frequency noise floor of a single S5 LIGO detector is roughly equivalent to a stochastic background spectrum with \( \Omega_{GW} = 0.01 \) (\( h_{GW} = 4 \times 10^{-23} \text{Hz}^{-1/2} \)) at 100 Hz). The cross-correlation measurement will be sensitive to a background \( \Omega_{GW} \) lower than this noise floor by a factor of \( \langle \gamma \rangle (T \Delta f)^{1/2} \). With a year of observation time and an effective bandwidth of 100 Hz this is a factor of several thousand, so we expect to probe for a stochastic background in the range \( \Omega_{GW} \sim 10^{-5} - 10^{-6} \). 

7.4.2. Analysis results. Since the SNR for a search on \( \Omega_{GW} \) grows inversely with the product of the strain noise amplitude spectra of the two detectors, the sensitivity of this search grew quickly as the detectors improved. Analysis of the S4 data yielded a Bayesian 90% upper limit of \( \Omega_{GW} < 6.5 \times 10^{-5} \) for a flat spectrum in the 51–150 Hz band [94]. Projecting for the S5 data, the lower strain noise and longer integration time should improve on this by an order of magnitude. While the cross-correlation analysis for S5 is in progress, it is straightforward to calculate the expected variance of the cross-correlation using only the interferometers’ strain noise spectra over the run. This predicts that the potential upper limit on \( \Omega_{GW} \) will be in the range \( (4-5) \times 10^{-6} \).

Such a result would be the first direct measurement to place a limit on \( \Omega_{GW} \) more stringent than the indirect bound set by big-bang-nucleosynthesis (BBN). The BBN bound, currently the most constraining bound in the band around 100 Hz, derives from the fact that a large GW energy density present at the time of BBN would have altered the abundances of the light nuclei in the universe [55, 92]. For the BBN model to be consistent with observations of these abundances, the total GW energy density at the time of nucleosynthesis is thus constrained. In the limiting case that the GW energy was confined to LIGO’s sensitive band of 50–150 Hz, the BBN bound is \( \Omega_{GW} < 1.1 \times 10^{-5} \) [55, 95].

The LIGO results are also being used to constrain the parameter space of models predicting a stochastic GW background, such as cosmic string models and pre-big-bang models [94]. The gamut of theoretical models and observations pertaining to a stochastic GW background spans an impressively wide range of frequencies and amplitudes. These are displayed in the landscape plot of figure 14.

The analysis described so far searches for an isotropic background of GWs. The cross-correlation method has also been extended to search for spatial anisotropies, as might be produced by an ensemble of astrophysical sources [96]. Such a GW radiometer requires spatially separated interferometers in order to point the multi-detector antenna at different locations on the sky. The result is a map of the power distribution of GWs convolved with the antenna lobe of the radiometer, with an uncertainty determined by the detector noise. Radiometer analysis of the S4 data yielded upper limits on the GW strain power from point sources in the range \( \sim 10^{-48} - 10^{-45} \text{Hz}^{-1} \), depending on sky position and the GW power spectrum model [97]. The S5 analysis should improve on the
Advanced LIGO will replace the existing interferometers with significantly improved technology to achieve a factor of at least 10 in sensitivity over the initial LIGO interferometers and to lower the seismic wall frequency down to 10 Hz [100, 101]. Advanced LIGO has been funded by the National Science Foundation, beginning in April 2008. Installation of the Advanced LIGO interferometers is planned to start in early 2011.

The Advanced LIGO interferometers are configured like initial LIGO—a power-recycled Fabry–Perot Michelson—with the addition of a signal recycling mirror at the antisymmetric output. Signal recycling gives the ability to tune the interferometer frequency response, so that the point of maximum response can be shifted away from zero frequency [9]. The laser wavelength stays at 1064 nm, but an additional high-power stage brings the laser power up to 200 W [102]. The test masses will be significantly larger—40 kg—in order to reduce radiation pressure noise and to allow larger beam sizes. Larger beams and better dielectric mirror coatings combine to reduce the test mass thermal noise by a factor of 5 compared with initial LIGO [103].

The test mass suspensions become significantly more intricate to provide much better performance. They incorporate four cascaded stages of passive isolation, instead of just one, including vertical isolation comparable to the horizontal isolation at all stages except one [104]. The test mass is suspended at the final stage with fused-silica fibers rather than steel wires; these fibers have extremely low mechanical loss and will reduce suspension thermal noise nearly a hundred-fold [105]. The current passive seismic isolation stacks that support the suspensions are replaced with two-stage active isolation platforms [106]. These stages are designed to actively reduce the ground vibration by a factor of ∼1000 in the 1–10 Hz band, and provide passive isolation at higher frequencies. The combination of the isolation platforms and the suspensions will reduce seismic noise to negligible levels above approximately 10 Hz.

The successful operation of Advanced LIGO is expected to transform the field from GW detection to GW astrophysics. We illustrate the potential using compact binary coalescences. Detection rate estimates for CBCs can be made using a combination of extrapolations from observed binary pulsars, stellar birth rate estimates and population synthesis models. There are large uncertainties inherent in all of these methods, however, leading to rate estimates that are uncertain by several orders of magnitude. We therefore quote a range of rates, spanning plausible pessimistic and optimistic estimates, as well as a likely rate. For a NS mass of 1.4$M_\odot$ and a BH mass of 10$M_\odot$, these rate estimates for Advanced LIGO are: 0.4–400 yr$^{-1}$, with a likely rate of 40 yr$^{-1}$ for NS–NS binaries; 0.2–300 yr$^{-1}$, with a likely rate of 10 yr$^{-1}$ for NS–BH binaries; 2–4000 yr$^{-1}$, with a likely rate of 30 yr$^{-1}$ for BH–BH binaries.
