Abstract. The feasibility of high-fidelity single-qubit operations on a hole spin in a quantum dot molecule by electric $g$ tensor control is demonstrated. Apart from a constant external magnetic field the proposed scheme allows for an exclusively electric control of the hole spin. Realistic electric gate bias profiles are identified for various qubit operations using process-tomography-based optimal control. They are shown to be remarkably robust against decoherence and dissipation arising from the interaction of the hole with host-lattice nuclear spins and phonons, with a fidelity loss of $\approx 1\%$ for gate operation times of $\approx 10$ ns. Spin-echo experiments for the hole spin are modeled to explore dephasing mechanisms and the role of pulse-timing imperfections in the gate fidelity loss is discussed.
1. Introduction

We propose and study the feasibility of all-electric control of a qubit realization based on the hole spin in a quantum dot molecule (QDM). This system offers two main advantages over electron-spin-based realizations: the use of hole spins increases the dephasing time associated with the interaction with nuclear spins by about an order of magnitude and allows for an efficient $g$ tensor control, thereby facilitating essentially all-electric control of the qubit.

Spin-based quantum bit realizations in semiconductor quantum dots (QDs) have gained wide interest in the quantum computing community due to their potential regarding scalability and their long relaxation times. Most work, both theoretical and experimental, has focused on electron spin qubits, which have spin relaxation times ranging from several milliseconds [1] to seconds [2]. However, it has turned out that this type of qubit is prone to decoherence processes due to the interaction with surrounding nuclear spins of the host lattice [3, 4]. The Fermi contact hyperfine interaction ultimately limits the inhomogeneous dephasing time to $T_{2e}^* \approx 10 \, \text{ns}$ [5]. Several techniques to circumvent this problem have been devised, e.g. nuclear state preparation [6]—[9], fabrication of silicon-based semiconductor heterostructures with zero nuclear magnetic moment [10] or employing hole spins instead of electron spins [11, 12]. The p-type symmetry of the hole Bloch function leads to cancellation of the Fermi contact hyperfine interaction. However, it has been shown that the dipole–dipole hyperfine interaction and the coupling of the hole orbital angular momentum to the nuclear spins cannot be neglected [13]–[15]. These lead to an inhomogeneous dephasing time $T_{2h}^*$ one order of magnitude longer than that of electrons [14], which is in good agreement with recent experiments [16].

Basic spin qubit implementation schemes usually require local magnetic fields for individual spin manipulations [17]. Another technique, which has been proposed and tested recently, is to exploit the tunability of electron-spin and hole-spin $g$ tensors by electric fields rather than employing control by local magnetic fields [18]–[21]. If an external magnetic
Figure 1. (a) Vertically stacked pyramidal QDs, dot spacing $d = 1.5$ nm, height $h = 2.5$ nm and width $w = 15$ nm. The coordinates $x$, $y$ and $z$ denote the [100], [010] and [001] directions, respectively. The origin of the coordinate system is indicated by 0. The external electric field points along the [001] direction, i.e. $\vec{E} = (0, 0, E)$. (b) Electric field dependence of the $g$ tensor elements. The solid and the dashed line denote $g_{001}^0(E)$ and $g_{1\bar{1}0}^1(E)$, respectively. (Data are taken from [21]).

In section 2, we describe the computational basis states of the qubit, the corresponding Hamiltonian and the mechanisms that lead to non-unitary dynamics. The equation of motion for the qubit, including decoherence and relaxation dynamics, is given. In section 3, we apply optimal control theory in order to find simple electric pulse shapes that execute the Hadamard gate, as well as a $\pi/2$ and a $\pi$ pulse. We find that these transformations can be implemented with remarkably low fidelity losses of $\approx 1\%$. In addition, we show how spin-echo experiments can be performed on the hole spin to explore decoherence in the system. We also discuss quantitatively the effect of pulse-timing imperfections. We conclude with a summary of the present work. The model for the interaction of the nuclear spins with the hole is detailed in appendices A and B.

2. Theory

In this section, we present the qubit realization and give the effective Hamiltonian for a single hole in a QDM composed of vertically stacked self-assembled InAs/GaAs QDs separated by a small tunnel layer. The detailed geometry of the QDM, which we use for the present study, is shown in figure 1(a). Two pyramidal dots (height $h$, width $w$) are stacked on top of each other and separated by a barrier of distance $d$. The QDM is exposed to a static magnetic field, as well as a time-dependent electric field applied along the [001] growth direction. It is controlled by a gate bias and used to modulate the hole $g$ factor by shaping the hole wavefunction [21]. The controlled growth of InAs/GaAs QDMs as well as the electric modulation of exciton $g$ factors in such structures has been demonstrated experimentally in [19].
Next to the interaction of the hole with the externally applied control fields, all contained in the effective Hamiltonian \( H_0 \), there will be additional (unwanted) interactions with the solid-state environment. Therefore, we account for the interaction of the host-lattice nuclear spins with the hole, develop a phenomenological description of the hole–phonon interaction and give the resulting equation of motion on which our analysis is based.

The first task is to compute the effective interaction of the hole with a constant external magnetic field. The interaction is characterized by a \( g \) tensor, which depends on the externally applied electric field, as shown in figure 1(b) [21]. We have performed three-dimensional 8-band envelope function calculations, including external fields, strain and piezoelectric polarization, in order to determine the QDM heavy-hole and light-hole components of the ground \( |\Psi_0\rangle \) and the first excited Zeeman state \( |\Psi_1\rangle \). Details of this method have been published elsewhere [22, 23]. For a vertical external magnetic field, the energy eigenstates \( |\Psi_0\rangle \) and \( |\Psi_1\rangle \) of the full 8×8 Hamiltonian correspond predominantly to heavy-hole (hh) down \( (j_z = +3/2) \) and hh up \( (j_z = -3/2) \) states, respectively. The conduction and split-off (SO) band contributions are neglected, since they are \( \lesssim 1\% \). However, light-hole (lh) contributions cannot be neglected. We write the hole wavefunctions as

\[
\langle \vec{r} | \Psi_k \rangle \equiv \Psi_k(\vec{r}) = \sqrt{\Omega} \sum_{j,j_z} F^{(k;j,j_z)}(E, \vec{r}) \psi^{(j,j_z)}(\vec{r}),
\]

\( j \in \left\{ \frac{3}{2}, \frac{1}{2} \right\}, \quad j_z \in \left\{ \pm \frac{3}{2}, \pm \frac{1}{2} \right\}, \quad k \in \{0, 1\},
\]

where \( F^{(k;j,j_z)}(E, \vec{r}) \) denotes the envelope function associated with the \( \Gamma \)-point basis function \( \psi^{(j,j_z)}(\vec{r}) \), which transforms like the eigenfunction \( |j, j_z\rangle \) of the angular momentum operator \( J_z \), and \( \Omega \) is the volume of the unit cell of the crystal. For zero electric field \( \vec{E} \) and for vertical magnetic field \( \vec{B} = (0, 0, 10) \) mT, the hh and lh contributions, respectively, are given by

\[
\int d\vec{r} \left\{ |F^{(k;3/2, +3/2)}(E, \vec{r})|^2 + |F^{(k;3/2, -3/2)}(E, \vec{r})|^2 \right\} \approx 0.909,
\]

\[
\int d\vec{r} \left\{ |F^{(k;3/2, +1/2)}(E, \vec{r})|^2 + |F^{(k;3/2, -1/2)}(E, \vec{r})|^2 \right\} \approx 0.075, \quad \text{with} \quad k \in \{0, 1\}.
\]

We have chosen our coordinate system along the cubic axes, where \( z \) is the growth direction of the QDs. In figures 2(a) and (b), respectively, we present contour plots of \( |F^{(1;3/2, -3/2)}(E, \vec{r})|^2 \) and \( |F^{(1;3/2, -1/2)}(E, \vec{r})|^2 \) in the \( x = 0 \) plane. The corresponding coordinate system is depicted in figure 1(a).

The energy difference between \( |\Psi_1\rangle \) and the next higher energy eigenstate \( |\Psi_2\rangle \) is larger than 1 meV, versus a splitting of \( \approx 0.4 \mu\text{eV} \) between the lowest two states. Hence, the system near the ground state is well described by a two-level system with basis states \( |\Psi_0\rangle \) and \( |\Psi_1\rangle \). These are essentially linear combinations of upper- and lower-dot hole states, with the admixture depending on the value of the external electric field. The effective Hamiltonian of the pseudo-spin system reads [21]

\[
H_0 = \frac{\mu_B}{2} \vec{\sigma} \cdot g(E) \cdot \vec{B},
\]

where \( \vec{\sigma} \), \( g(E) \) and \( \vec{B} \), respectively, denote the Pauli matrix vector of the pseudo-spin-\( \frac{1}{2} \) system, the electrically tunable hole \( g \) tensor and the externally applied magnetic field. Note that
Figure 2. Spatial dependence of the envelope functions $|F^{(1;3/2, j_z)}(E, \vec{r})|^2$ within the $x = 0$ plane (see figure 1(a)) for (a) the hh contribution with $j_z = -3/2$ and (b) for the lh contribution with $j_z = -1/2$. All envelope functions are given for $E = 0$ kV cm$^{-1}$ and $\vec{B} = (0, 0, 10)$ mT. The cross-sections of the pyramidal QDs are indicated by red dashed lines.

The corresponding interaction Hamiltonian of a single nuclear spin with a hole has the form [24]

$$H'_i = 2\mu_B \gamma_i \vec{I}_i \cdot \left[ \frac{\vec{I}_i}{\rho_i^3} - \frac{\vec{s}}{\rho_i^3} + 3\vec{\rho}_i (\vec{s} \cdot \vec{\rho}_i) \right],$$

where $\vec{I}_i$ denotes the $i$th nuclear-spin operator and $\gamma_i$ and $\mu_B$, respectively, denote the gyromagnetic ratio of the $i$th nuclear spin and the Bohr magneton. The hole spin operator

$$H_0 = \frac{\mu_B}{\sigma} \left[ \begin{array}{ccc} \frac{g^{110} + g^{110}}{2} & \frac{g^{110} - g^{110}}{2} & 0 \\ \frac{g^{110} + g^{110}}{2} & \frac{g^{110} - g^{110}}{2} & 0 \\ 0 & 0 & g^{001} \end{array} \right] \left[ \begin{array}{c} B \\ -B \\ B \end{array} \right] = \frac{\mu_B}{2} B [(\sigma_x - \sigma_y) g^{110} + g^{001} \sigma_z].$$

Throughout this paper, we choose a value of $B = 10$ mT and an external electric field pointing along the [001] direction, $\vec{E} = (0, 0, E)$. A non-vanishing in-plane magnetic field is necessary in order to obtain full control over the qubit.

2.1. Hole–nuclear-spin interaction

In addition to the externally applied magnetic field, the hole experiences an effective magnetic field that results from the nuclear spins of the host lattice. This is a consequence of the non-vanishing dipole–dipole hyperfine interaction (in contrast to the Fermi contact hyperfine interaction that vanishes for wavefunctions of p-symmetry), as well as the coupling of the hole orbital angular momentum to the nuclear spins [14, 15]. We now determine this effective field.
is denoted by $\mathbf{s}$, $\mathbf{p}_i \equiv \mathbf{r} - \mathbf{R}_i$ is the distance vector between the hole and the $i$th nuclear spin (located at $\mathbf{R}_i$), and $\hat{l}^i = \mathbf{p}_i \times \hat{p}$ denotes the hole orbital angular momentum operator. We note that $\mathbf{r}$ and $\mathbf{R}_i$ are given in the coordinate system introduced in figures 1(a) and 2(a) and (b). The matrix elements of $H_1$ are now calculated in the $\{|\Psi_0\rangle, |\Psi_1\rangle\}$ basis defined above. We closely follow the approach given in [13, 15] and obtain

$$
\langle \Psi_k | H_1^i | \Psi_i \rangle \equiv \sum_{j_i,j_i'} [F^{(k,j_i')}(E, \mathbf{R}_i)]^* F^{(l,j_i,j_i')}(E, \mathbf{R}_i) V_{j_i,j_i'}^{i}.
$$

(6)

The matrix elements with respect to the four basis functions $\{\psi^{(i,\frac{1}{2})}, \psi^{(i,\frac{3}{2})}, \psi^{(i,\frac{-1}{2})}, \psi^{(i,\frac{-3}{2})}\}$ are given by

$$
V_{j_i,j_i'}^{i} \equiv c_i \begin{bmatrix}
I_z^i & \frac{1}{\sqrt{3}} I_x^i & 0 & 0 \\
\frac{1}{\sqrt{3}} I_x^i & \frac{1}{3} I_z^i & \frac{2}{3} I_z^i & 0 \\
0 & \frac{2}{3} I_z^i & -\frac{1}{3} I_z^i & \frac{1}{\sqrt{3}} I_y^i \\
0 & 0 & \frac{1}{\sqrt{3}} I_y^i & -I_z^i 
\end{bmatrix}.
$$

(7)

where $I_\pm^i = I_x^i \pm I_y^i$ and $I_z^i$ are the nuclear-spin operators and

$$
c_i = \frac{8 \mu_B \gamma \hbar \Omega}{5} \int_0^{R_0} \rho d\rho \left| \kappa(\rho) \right|^2.
$$

(8)

The integration in equation (8) extends over the dominant part of the interaction defined by a radius $R_0$ around the nuclear spin under consideration and $\kappa(\rho)$ is the radial part of the basis functions. The details of the calculation are given in appendix A. Finally, the interaction of the ensemble of nuclear spins with the two-level system can be cast into the form

$$
H_{\text{nuc}}(\vec{B}_n) = \sum_i H_i^i = \frac{\mu_B}{2} \mathbf{\hat{s}} \cdot \vec{B}_n,
$$

(9)

where $i$ runs over all $N \approx 10^4$–$10^5$ nuclear spins interacting with the hole. This has the form of the interaction of the pseudo-spin with an effective operator-valued magnetic field $\vec{B}_n$. The dynamics of the hole is much faster than that of the nuclear spins. This allows one to employ a quasi-static approximation for $\vec{B}_n$ for the time period of a single measurement (initialization, manipulation and readout) of the hole spin qubit so that $\vec{B}_n$ may be approximated by a classical constant vector [3, 4, 25]. During the time it takes to perform $10^3$–$10^4$ repetitions of the measurement, the effective magnetic field varies significantly, leading to inhomogeneous-broadening-type dynamics [25]. The simplest way to take into account this variation is to treat the vector components of $\vec{B}_n = (B_n^x, B_n^y, B_n^z)$ as random variables with Gaussian probability distributions [3, 4, 25]

$$
P(\vec{B}_n) = P(B_n^x) P(B_n^y) P(B_n^z) \quad \text{with} \quad P(B_n^i) = \frac{1}{\sqrt{2\pi} \Delta_i} \exp \left[ - (B_n^i - \langle B_n^i \rangle)^2 / (2 \Delta_i^2) \right].
$$

(10)

Here, $P(B_n^i)$ is the probability of finding a value $B_n^i$ for the effective nuclear magnetic field along the $i$-direction and $\Delta_i^2 \equiv \langle B_n^i B_n^i \rangle - \langle B_n^i \rangle^2$ denotes the corresponding variance of the effective

4 Note that we find positive signs for the matrix elements $V_{i/2,-1/2}^{i}$ and $V_{-i/2,1/2}^{i}$ in contrast to [15].
magnetic field fluctuation. We assume an ‘infinite temperature’ nuclear-spin density matrix, i.e. \( \rho_n = (2I + 1)^{-N/2} \) [4]. Hence, the mean values \( \langle B_n^i \rangle \) vanish for all directions \( i \). Furthermore, we assume that the spin bath is uncorrelated, i.e. \( \langle B_n^i B_n^j \rangle = 0 \) for \( i \neq j \). Finally, the total Hamiltonian of the system reads

\[
H(\vec{B}_n) = H_0 + H_{\text{nuc}}(\vec{B}_n).
\]

We note that \( H(\vec{B}_n) \) is time dependent via the electric field that is applied to control the hole dynamics.

In a recent experiment, the dephasing time of a hole spin in a single QD has been determined to be at least \( T_{2,h} \approx 100 \text{ ns} \) [16]. This corresponds to a variance of \( \Delta_x = h/(\mu_B T_{2,h}) \approx 0.1 \text{ mT} \) [25]. We use this value for our simulation of the hole–nuclear-spin interaction. The variances \( \Delta_x \) and \( \Delta_y \) are calculated in appendix B. We find that \( \Delta_x/\Delta_z \approx \Delta_y/\Delta_z \approx 10^{-1} \).

2.2. Hole–phonon interaction

The coupling of the hole to acoustic phonons via the piezoelectric and deformation potential interactions leads to additional dephasing and relaxation [26]. To account for these mechanisms, we employ a Lindblad model [27]. The dissipator reads

\[
\mathcal{D} [\rho] = \Gamma_\downarrow \left[ \sigma_- \rho \sigma_+ - \frac{1}{2} \{ \sigma_+ \sigma_- , \rho \} \right] + \Gamma_\uparrow \left[ \sigma_+ \rho \sigma_- - \frac{1}{2} \{ \sigma_- \sigma_+ , \rho \} \right] + \frac{\Gamma_{\text{ph}}}{2} \left[ \sigma_z \rho \sigma_z - \rho \right],
\]

with \( \Gamma_\downarrow \), \( \Gamma_\uparrow \) and \( \Gamma_{\text{ph}} \) denoting the relaxation rates for the transitions \( |\Psi_0\rangle \rightarrow |\Psi_0\rangle \), \( |\Psi_0\rangle \rightarrow |\Psi_1\rangle \) and the pure dephasing rate, respectively. The braces denote anticommutators. For simplicity, we set \( \Gamma_{\text{ph}} = \Gamma_\downarrow = \Gamma_\uparrow \equiv \Gamma \). The range of reported relaxation times varies significantly with temperature and the externally applied magnetic field [28, 29]. For this work, we choose a relatively conservative value of \( T_{1,h} = 1 \mu s = 1/(\Gamma_\downarrow + \Gamma_\uparrow) = 1/\Gamma \). We note that the hole relaxation rate for QDs due to phonon interaction does not increase with decreasing external magnetic field [12, 26, 28, 30].

2.3. Hole-spin dynamics

Inspection of figure 1(b) reveals that the \( g \) tensor component \( g^{001}(E) \) cannot be tuned to 0, in contrast to \( g^{110}(E) \). For a simpler description of the hole-spin dynamics, it is therefore useful to switch to a rotating frame \( |\psi\rangle \rightarrow |\psi\rangle \equiv U_2 |\psi\rangle \), which rotates around the \( z \)-axis with a frequency given by

\[
\omega^* = \mu_B g^{001}(E^*) B/\hbar.
\]

The transformation is characterized by the time-dependent unitary operator \( U_2 \equiv \exp(\omega^* t \sigma_z/2) \), where the electric field \( E^* \) is defined by the relation

\[
g^{110}(E^*) = 0.
\]

In addition, we perform another \textit{time-independent} rotation \( U_1 = e^{-i(\pi/8)\sigma_z} \), which corresponds to the pseudo-spin rotation \( \sigma_x - \sigma_y \rightarrow \sqrt{2} \sigma_z \) in equation (4). In this rotating coordinate system
(labeled by a tilde), the Lindblad equation for the density matrix reads

\[
\dot{\tilde{\rho}}(\vec{B}_n, t) = U_2 U_1 \rho(\vec{B}_n, t) U_1^\dagger U_2^\dagger,
\]

\[
\frac{d\tilde{\rho}(\vec{B}_n, t)}{dt} = -\frac{i}{\hbar} [H_r(\vec{B}_n), \tilde{\rho}(\vec{B}_n, t)] + \tilde{\mathcal{D}}[\tilde{\rho}(\vec{B}_n, t)], \tag{15}
\]

\[
H_r(\vec{B}_n) = U_2 U_1 H(\vec{B}_n) U_1^\dagger U_2^\dagger + i \hbar \frac{dU_2}{dt} U_2^\dagger,
\]

with \(H(\vec{B}_n)\) given in equation (11). It can be shown that \(\tilde{\mathcal{D}}[\tilde{\rho}(\vec{B}_n, t)] = \mathcal{D}[\tilde{\rho}(\vec{B}_n, t)]\), i.e. the form of the dissipator is invariant under the coordinate transformations described above. The density matrix has to be averaged over the effective nuclear magnetic field \(\vec{B}_n\) of each measurement. It is calculated by averaging over typically \(M = 3000\) values of the random effective nuclear magnetic field with probability distributions as given in equation (10), using

\[
\tilde{\rho}(t) = (1/M) \sum_M \tilde{\rho}(\vec{B}_n). \tag{16}
\]

### 3. Results

#### 3.1. Pulse shape optimization

In the previous section, we have detailed the hole-spin qubit and identified a complete control mechanism. We are now in a position to find optimal electric fields that perform any type of qubit transformation. However, the dependence of the \(g\) tensor elements on the electric field \(E\) is a complex one, as can be seen in figure 1(b). Therefore, appropriate control fields can, in general, not be determined analytically, particularly, if the finite rise time of the electric control is to be taken into account. Here, we apply optimal control theory in order to determine both realistic and simple pulse shapes.

We start by outlining how to characterize qubit operations. For single-qubit systems, quantum gate transformations can be described as rigid rotations of the Bloch sphere. For unitary dynamics, this rotation can be fully described by the time evolution propagator \(U(t)\) corresponding to the Hamiltonian \(H_r(\vec{B}_n)\) given in equation (15). However, it is more advantageous to employ the so-called process tomography matrix (PTM) \(\chi(t)\). For strictly unitary dynamics, this matrix takes the simple form [31]

\[
\chi(t) = U(t)^* \otimes U(t), \tag{17}
\]

with \(U(t)^*\) denoting the complex conjugate of the matrix representation of \(U(t)\). The PTM eliminates physically irrelevant global phases of the propagator \(U \rightarrow e^{i\Phi} U\), can be readily obtained in experiments [32]–[34] and can be employed for non-unitary dynamics as well [35, 36].

The next step is to define a cost functional that quantitatively reflects how accurately a control field achieves a given unitary gate transformation. We use the PTM of equation (17) that implicitly depends on the electric field, \(\chi(t) = \chi[E(t); t]\), and seek electric pulse shapes that minimize the following cost functional [37]:

\[
J[E] = \text{tr} \left\{ \left[ \chi(t_f) - \chi_D \right] \left[ \chi(t_f) - \chi_D \right]^\dagger \right\}, \tag{18}
\]
where $\chi_D$ denotes the ideal PTM and the interval $(0, t_f)$ is the time span allowed for the gate transformation (gate operation time). A perfect implementation of the given unitary gate transformation corresponds to $J = 0$. Other distance measures for open quantum systems are given in [38]–[42]. We choose the following analytic form of the electric control field:

$$E(t) = E^* + \sum_{j=1}^{M} \frac{A_j}{4} \left\{ 1 + \tanh \left[ \alpha \left( t - \sum_{i=1}^{j} \Delta t_i \right) \right] \right\} \left\{ 1 + \tanh \left[ \alpha \left( \sum_{i=1}^{j} \Delta t_i - t \right) \right] \right\},$$  (19)

where $A_j$ and $\Delta t_j$ are the parameters to be optimized and $E^*$ is the working point defined by equation (14). The pulse form of equation (19) corresponds to a sequence of $M$ voltage steps of amplitude $A_j$, each of duration $\Delta t_j$. The finite rise time of the pulses is determined by the parameter $\alpha$ that we set to $\alpha = 8.79 \text{ ns}^{-1}$. The optimal control field $E_{\text{opt}}(t)$ is obtained from the minimization procedure

$$J_{\text{opt}}[E_{\text{opt}}] = \min_{\{A_j, \Delta t_j\}} J[E(A_j, \Delta t_j)].$$  (20)

We then use the optimal control field $E(t) = E_{\text{opt}}(t)$ to determine the PTM with dephasing and relaxation included in our simulations. We note that, in the non-unitary case, $\chi(t)$ is no longer given by equation (17) but can be computed by using equations (15) (see [37] for details of this calculation). However, the form of the cost functional given in equation (18) does not change. Thus, a value $J > 0$ reflects suboptimal pulse shaping and/or the presence of decoherence and relaxation effects. In addition to $J$, it is customary to define a fidelity loss of the gate operation by

$$\Delta F[E] = \left( J[E] / J_{\text{max}} \right)^{1/2},$$  (21)

with $J_{\text{max}} = 2n^2$, where $n$ denotes the number of basis states of the quantum system, i.e. $n = 2$ for single qubits. A perfect execution of the gate operation corresponds to $\Delta F[E] = 0$. For brevity, we will write $\Delta F$ instead of $\Delta F[E]$ throughout this work.

We perform the cost functional minimization (equation (20)) for both the Hadamard operation (which transforms the axes of the Bloch sphere as follows: $x \rightarrow z$, $z \rightarrow x$ and $y \rightarrow -y$) and a $\pi/2$ rotation around the $y$-axis. The corresponding unitary evolution operators $U_H$ and $U_{\pi/2}$ and the ideal PTM $\chi_H$ and $\chi_{\pi/2}$, respectively, read (see equation (17))

$$U_H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}, \quad U_{\pi/2} = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix},$$

$$\chi_H = (U_H)^* \otimes U_H, \quad \chi_{\pi/2} = (U_{\pi/2})^* \otimes U_{\pi/2}.$$

We set the gate operation time $t_f = 10 \text{ ns}$. The minimization is executed within a differential evolution algorithm [43]. For the Hadamard gate, the algorithm converges to an optimal control field that consists of three pulses, depicted in figure 3(a). The $\pi/2$ rotation, on the other hand, is realized by an optimal control field consisting of four pulses, as shown in figure 3(c). Trajectories of the Bloch vector for both transformations with equal initial states ($\Psi_1$) are given in figures 3(b) and (d).

If we do not account for decoherence and relaxation in our simulations, the fidelity losses due to imperfect pulse shaping are of the order $\Delta F \approx 0.001\%$. When decoherence and relaxation are included, the fidelity loss increases to $\Delta F \approx 1\%$, which gives excellent
Figure 3. (a) Optimal electric pulse shape $E_{\text{opt}}(t)$ for the Hadamard transformation and (c) for the $\pi/2$ rotation. The dot-dashed red lines correspond to $E = E^*$ given in equation (14). (b) The trajectory of the Bloch vector for the Hadamard gate and (d) for the $\pi/2$ pulse. The final states of both transformations coincide for the initial state $\Psi_1$, although the trajectories of the Bloch vectors differ.

Figure 4. (a) Real part of the matrix elements $(m, n)$ of the optimal Hadamard PTM $\chi(t_f)$. (b) Deviation of the optimal PTM with respect to $\chi_H$ (relaxation and dephasing included). The corresponding fidelity loss is $\Delta F \approx 1\%$.

performance. The contributions to the fidelity loss due to phonons and nuclear spins are approximately of the same order. For the Hadamard gate, the real parts of the matrix elements $(m, n)$ of the optimal PTM, $\text{Re}[\chi(t_f)_{mn}]$, as well as the deviation of the optimal PTM from the ideal PTM $\chi_H$, are shown in figures 4(a) and (b), respectively.

3.2. Hole-spin echo

It is frequently important to analyze the characteristics of dephasing processes of a quantum system that are not associated with inhomogeneous dephasing, such as caused by the hole–nuclear-spin interaction discussed in section 2.1 in the present case. This can be achieved with spin-echo experiments [44]. The decay of the peak value of the spin-echo recovery signal gives information about the additional cumulative dephasing rate and the time dependence of the coherence loss (e.g. exponential versus polynomial decay).
Figure 5. (a) Schematic spin-echo sequence as described in the main text. The red (dark gray) arrow denotes the Bloch vector. (b) Time dependence of the coherence $\text{Re}[\tilde{\rho}_{01}(t)]$. The spike at $t \approx 0.4 \mu s$ is a consequence of the $\pi$-pulse. At $t \approx 0.8 \mu s$, a partial revival of coherence can be observed. (c) The solid black lines denote spin-echo signals for different pulse separation times $t_1$. The decrease of the peak echo signal is denoted by the red dot-dashed line.

In figure 5(a), we show the crucial steps that are needed to perform a spin-echo experiment for the hole-spin qubit.

(i) At time $t = 0$, one applies a $\pi/2$ pulse such as given in figure 3(c). It transforms the initial qubit state $|\Psi_1\rangle$ into the superposition state $1/\sqrt{2} (|\Psi_0\rangle + |\Psi_1\rangle)$ [44].

(ii) Subsequently, the Bloch vector of the qubit evolves according to the system dynamics, including dissipation, decoherence and the effective magnetic field from the nuclear spins. The latter causes a rotation of the Bloch vector around a random axis, given by the direction of $\vec{B}_n$.

(iii) At time $t_1 > 0$, one applies a $\pi$ pulse that is composed of two subsequent $\pi/2$ pulses. It rotates the Bloch vector by an angle $\pi$ around the $y$-axis of the Bloch sphere.

(iv) Next, the Bloch vector evolves again.

(v) At time $t = 2t_1$, the coherence, represented by $\text{Re}[\tilde{\rho}_{01}(t)]$, is partly restored.

Here, $\tilde{\rho}_{01}(t)$ is the off-diagonal matrix element of the density matrix $\tilde{\rho}(t)$ in the pseudo-spin basis (see equation (16)) and serves as a measure for coherence. For $t_1 \approx 0.4 \mu s$, a plot of its time evolution during a spin-echo experiment, as obtained within our model, is shown in figure 5(b). Spin-echo signals corresponding to different pulse separation times $t_1$ are given in figure 5(c). Since relaxation and pure dephasing due to the spin–phonon interaction are included in our simulation, the restoration of coherence is obtained as imperfect. The peak values of the echoes decrease approximately as $\sim \exp\{-2t_1[(\Gamma_1 + \Gamma_\downarrow)/2 + \Gamma_{\Phi_1}^\downarrow]\}$, indicated by the red dot-dashed line.
in figure 5(c). We note that the non-vanishing transversal nuclear magnetic field components $B_{x}^n$ and $B_{y}^n$ can also lead to a reduction of the peak value of the echo signal. However, we have analyzed this effect and, for the present system, have found the spin-echo signal due to longitudinal contributions and that due to longitudinal and transversal contributions (such as given in figures 5(b) and (c)) to be congruent.

3.3. Pulse timing imperfections

As mentioned above, the $\pi$-pulse of the proposed spin-echo sequence is composed of two subsequent $\pi/2$ pulses. Due to the form of the Hamiltonian in equation (15), these composite pulses should be applied at special times (integer multiples of $t_R = 2\pi/\omega^*$ after state initialization) in order to preserve the high fidelity of the gate transformation. This requirement is due to the effective magnetic field $g(E) \cdot \vec{B}$ along the z-direction that cannot be tuned to zero by electric means. The dependence of the fidelity loss $\Delta F$ with respect to a pulse delay time error $\delta$ between two subsequent $\pi/2$-pulses is shown in figure 6. This figure illustrates that the additional fidelity loss $\Delta F$ is smaller than 1% as long as $\delta \leq 10$ ps, which should be readily within the reach of present-day experiments. The sensitivity to the delay time error can be further decreased by reducing the magnitude of the external magnetic field.

4. Summary

We propose a qubit realization in the form of the spin of a hole in a QDM, which is controlled all-electrically by $g$ tensor modulation, and evaluate its performance regarding controllability and dissipative effects. The growth of InAs/GaAs QDMs and the electric control of excitonic $g$ tensors have already been demonstrated in the laboratory [19]. An effective qubit model for such a QDM is derived from a detailed electronic structure calculation, as well as from the inclusion of the interaction with nuclear spins of the host lattice and phonons. In [21], the methods of this electronic structure calculation have been used to describe the $g$ tensor modulation observed in [19] and have shown excellent agreement with the experiment. On the basis of the effective qubit model, we predict that high-fidelity gate operations for a single hole within a QDM are experimentally feasible and promising.
The qubit can be fully controlled by means of an external electric field $E$ that leads to a change of the effective magnetic field $g(E) \cdot \vec{B}$. In the present work, a constant magnetic field of the order of $|\vec{B}| \approx 10\, \text{mT}$ leads to a moderate time scale of the qubit dynamics and therefore ensures the experimental feasibility of the qubit control. We use optimal control methods in order to determine simple electric control pulses, as illustrated for the Hadamard gate and for a $\pi/2$ qubit rotation around the $y$-axis of the Bloch sphere. The 10 ns pulse profiles consist of voltage steps with a finite rise time that can be generated in experiment by arbitrary waveform generators. The performance of the gate transformations is tested with respect to dephasing and relaxation due to the interaction of the hole spin with the surrounding nuclear spins of the host lattice and due to the hole–phonon interaction. For electric pulses of duration 10 ns, we find that qubit manipulations can be performed with a remarkably low fidelity loss of $\Delta F \approx 1\%$.

We propose a spin-echo experiment that allows one to completely cancel inhomogeneous dephasing due to the hole–nuclear-spin interaction. Therefore, it would enable the experimenter to study and characterize additional dephasing mechanisms beyond inhomogeneous broadening. We also investigate the influence of pulse-timing imperfections on the gate fidelity. Our findings show that the additional fidelity loss is $\lesssim 1\%$ for pulse delay time errors of less than 10 ps.

Appendix A. Matrix elements of the hole–nuclear-spin Hamiltonian

In this section, we derive the matrix elements of equation (6). For simplicity, we omit the nuclear spin index $i$. The interaction Hamiltonian of a nuclear spin $\vec{l}$ (located at $\vec{R}$) with a hole reads (see section 2.1 and [24]),

$$H_I(\vec{\rho}, \vec{p}) = 2\mu_B\gamma \vec{l} \cdot \left( \frac{\vec{s}}{|\vec{\rho}|^3} - \frac{3\vec{\rho} \cdot \vec{s}}{|\vec{\rho}|^3} \right) + \frac{3\vec{s} \cdot \vec{\rho}}{|\vec{\rho}|^5},$$

or, using spin-resolved zone center valence-band Bloch functions $\psi^{(i,\alpha)}$, as

$$\psi_k(\vec{r}) = \sqrt{\Omega} \sum_{j, j_z} F^{(k,j,j_z)}(E, \vec{r}) \psi^{(j,j_z)}(\vec{r}), \quad j_z \in \left\{ \pm \frac{3}{2}, \pm \frac{1}{2} \right\}, \quad j \in \left\{ \frac{3}{2}, \frac{1}{2} \right\}, \quad k \in \{0, 1\}, \quad i \in \{ X, Y, Z \}, \quad \alpha \in \{ \uparrow, \downarrow \}, \quad k \in \{0, 1\}.$$
The matrix that describes the transformation between \( \psi^{(j,i)} \) and \( \psi^{(i,a)} \) is given in equation (A.8) [23, 45]. The wavefunctions \( \Psi_0(\vec{r}) \) and \( \Psi_1(\vec{r}) \) denote the ground and the first excited Zeeman state of the QDM. We neglect states with higher energy (see section 2) and calculate the matrix elements of the interaction Hamiltonian

\[
H_1(\vec{\rho}, \vec{p}) = \begin{bmatrix}
\langle \Psi_1 | H_1(\vec{\rho}, \vec{p}) | \Psi_1 \rangle & \langle \Psi_1 | H_1(\vec{\rho}, \vec{p}) | \Psi_0 \rangle \\
\langle \Psi_0 | H_1(\vec{\rho}, \vec{p}) | \Psi_1 \rangle & \langle \Psi_0 | H_1(\vec{\rho}, \vec{p}) | \Psi_0 \rangle
\end{bmatrix},
\]

(A.5)

with

\[
\langle \Psi_k | H_1(\vec{\rho}, \vec{p}) | \Psi_l \rangle = \Omega \sum_{i,j,a,\beta} \int_V d\vec{\rho} d\vec{\tau} \left\{ [F^{(k,i,a)}(E, \vec{\tau} + \vec{R}) \psi^{(j,i,a)}(\vec{\tau} + \vec{R})]^* \times \langle \vec{\tau} | H_1(\vec{\rho}, \vec{p}) | \vec{\rho} \rangle \psi^{(j,i,a)}(\vec{\rho} + \vec{R}) F^{(l,j,\beta)}(E, \vec{\rho} + \vec{R}) \right\},
\]

where \( \vec{R} \) denotes the position of the nuclear spin with respect to the coordinate system given in figures 1(a) and 2(a) and (b) and with \( \vec{\tau} = \vec{r} - \vec{R} \) denoting a spatial coordinate. Since the hole–nuclear-spin interaction is short ranged, we can assume that it is non-vanishing only within a sphere of volume \( V_{R_0} \) and radius \( R_0 \) around the nuclear spin [13]. Furthermore, the envelope functions are approximately constant within this sphere, i.e.

\[
\langle \Psi_k | H_1(\vec{\rho}, \vec{p}) | \Psi_l \rangle \\
\approx \Omega \sum_{i,j,a,\beta} \left[ F^{(k,i,a)}(E, \vec{R})]^* F^{(l,j,\beta)}(E, \vec{R}) \int_{V_{R_0}} d\vec{\rho} \left[ \psi^{(i,a)}(\vec{\rho})^* \right] H_1(\vec{\rho}, -i\hbar \vec{\nabla}_\rho) \psi^{(j,\beta)}(\vec{\rho}),
\]

(A.6)

where we used the spatial periodicity of \( \psi^{(i,a)}(\vec{\rho}) \) and \( \langle \vec{\tau} | H_1(\vec{\rho}, \vec{p}) | \vec{\rho} \rangle = H_1(\vec{\rho}, -i\hbar \vec{\nabla}_\rho) \delta(\vec{\rho} - \vec{\tau}) \). In fact, it can be shown that \( V_{R_0} \) is well approximated by the unit cell around the nuclear spin under consideration. Contributions due to long range interactions lead to corrections of the order of 1% [14, 15]. Following [13], we employ a spherical approximation of the basis functions \( \psi^{(i,a)}(\vec{\rho}) \). Using spherical coordinates \( (\rho, \theta, \phi) \), the corresponding approximate basis functions read

\[
\psi^{(X,a)}(\rho, \theta, \phi) \approx \sqrt{\frac{3}{4\pi}} \kappa(\rho) \sin(\theta) \cos(\phi) |\alpha\rangle,
\]

\[
\psi^{(Y,a)}(\rho, \theta, \phi) \approx \sqrt{\frac{3}{4\pi}} \kappa(\rho) \sin(\theta) \sin(\phi) |\alpha\rangle,
\]

\[
\psi^{(Z,a)}(\rho, \theta, \phi) \approx \sqrt{\frac{3}{4\pi}} \kappa(\rho) \cos(\theta) |\alpha\rangle.
\]

Here, \( \kappa(\rho) \) denotes the radial part of \( \psi^{(i,a)}(\rho, \theta, \phi) \) and \( |\alpha\rangle \) is a ket in the spin basis \{↑, ↓\}. An estimation of the magnitude of the hole–nuclear-spin interaction is given in [14], where the authors used a linear combination of atomic orbitals for the hh Bloch function. In the
basis \( \psi^{(i,\alpha)}[\alpha, \beta \in \{\uparrow, \downarrow\} \text{ and } i, \ j \in \{X, Y, Z\}] \) and by employing the aforementioned spherical approximation, the integral \( V_{ij\alpha\beta} \) (equation (A.6)) can be expressed as

\[
\frac{V_{ij\alpha\beta}}{\Omega} = 2\mu_B\gamma I_m \int_0^{R_0} d\rho \frac{\kappa(\rho)^2}{\rho} \left[ -i\hbar\epsilon_{ij\alpha\beta} - \frac{2}{5} \left( \delta_{ij}\delta_{mn} - \frac{3}{2} \left( \delta_{im}\delta_{jn} + \delta_{in}\delta_{jm} \right) \right) \langle \alpha | s_n | \beta \rangle \right]. \tag{A.7}
\]

A discussion of modifications of the interaction at small \( \rho \) due to the finite size of the nucleus can be found in [46].

Since we want to express the hole–nuclear-spin interaction in terms of \( \ell h \) and \( hh \) contributions, we change the basis representation of \( V_{ij\alpha\beta} \) from \( \{\psi^{(i,\alpha)}\} \) to \( \{\psi^{(j;\beta)}\} \). The transformation is governed by the unitary matrix [23, 45]

\[
U_{\lambda\nu} = \frac{1}{\sqrt{6}} \begin{bmatrix}
-\sqrt{3} & 0 & i\sqrt{3} & 0 & 0 & 0 \\
0 & -1 & 0 & i & 2 & 0 \\
1 & 0 & i & 0 & 0 & 2 \\
0 & \sqrt{3} & 0 & i\sqrt{3} & 0 & 0 \\
0 & -\sqrt{2} & 0 & i\sqrt{2} & -\sqrt{2} & 0 \\
-\sqrt{2} & 0 & -i\sqrt{2} & 0 & 0 & \sqrt{2}
\end{bmatrix}, \tag{A.8}
\]

where the new matrix representation \( \tilde{V} \) is given by \( \tilde{V}_{\mu\nu} = U_{\mu\sigma} V_{\sigma\lambda} U_{\nu\lambda}^\dagger \). Here, we use the shorthand notation

\[
\mu, \nu = (j, j_z) \in \left\{ (\frac{3}{2}, \frac{3}{2}), (\frac{3}{2}, \frac{1}{2}), (\frac{3}{2}, \frac{1}{2}), (\frac{3}{2}, \frac{1}{2}), (\frac{1}{2}, \frac{1}{2}), (\frac{1}{2}, \frac{1}{2}) \right\},
\]

\[
\sigma, \lambda = (i, \alpha) \in \left\{ (X, \uparrow), (X, \downarrow), (Y, \uparrow), (Y, \downarrow), (Z, \uparrow), (Z, \downarrow) \right\}. \tag{A.9}
\]

The transformed matrix \( \tilde{V}_{\mu\nu} \) in the \( \{\psi^{(3/2,+3/2)}, \psi^{(3/2,+1/2)}, \psi^{(3/2,-1/2)}, \psi^{(3/2,-3/2)}\} \) basis thus reads

\[
\tilde{V}_{\mu\nu} = \frac{8\mu_B\gamma\hbar\Omega}{5} \int_0^{R_0} d\rho \frac{\kappa(\rho)^2}{\rho} \begin{bmatrix}
I_z & \frac{1}{\sqrt{3}} I_+ & 0 & 0 \\
\frac{1}{\sqrt{3}} I_+ & \frac{2}{3} I_+ & \frac{2}{3} I_- & 0 \\
0 & \frac{2}{3} I_+ & -\frac{1}{3} I_+ & \frac{2}{3} I_- \\
0 & 0 & \frac{2}{3} I_+ & -\frac{1}{3} I_-
\end{bmatrix} \equiv \tilde{V}_{j_z;j_z}. \tag{A.10}
\]

Split-off contributions \( (j = \frac{1}{2}) \) have been neglected as discussed in section 2. We finally arrive at the expression

\[
\langle \Psi_k | H_1(\vec{\rho}, \vec{p}) | \Psi_l \rangle \approx \sum_{j_z,j_z'} \left[ F^{(k;j_z=j_z';j_z)}(E, \vec{R}) \right] F^{(l;j_z=j_z',j_z)}(E, \vec{R}) \tilde{V}_{j_z;j_z}, \tag{A.11}
\]

for the \( \{\mid \Psi_0 \rangle, \mid \Psi_1 \rangle \} \) matrix representation of the hole–nuclear-spin interaction (for the definition of \( \tilde{V}_{j_z;j_z} \), see equation (A.10)).

The Wigner–Eckart theorem can be used to determine the matrix elements of the hole–nuclear-spin interaction as well [47]–[49]. In addition to the calculation presented above, we decomposed the spatial part of equation (A.1) into spherical tensors \( \tilde{I}_m \) and \( \tilde{Q}_{mn} \),

\[
l_m/\rho^5 \to \tilde{l}_m, \quad \frac{\rho^2\delta_{mn} - 3\rho_m\rho_n}{\rho^5} \to \tilde{Q}_{mn}, \tag{A.12}
\]

which correspond to angular momenta \( j = 1 \) and \( j = 2 \), respectively. The Wigner–Eckart theorem can then be readily applied to obtain the matrix elements in terms of Clebsch–Gordan
Appendix B. Variances of the effective nuclear magnetic field

Here, we derive the expression for the effective nuclear magnetic field $\vec{B}_n$ given in equation (9), as well as the ratio of the variances $\Delta_1$ and $\Delta_2$ with respect to $\Delta_3$ (equations (10)). We rewrite equation (A.11) into

$$
\langle \Psi_k | H_\lambda (\vec{\rho}, \vec{p}) | \Psi_l \rangle = c [A_{kl} (E, \vec{R}) I_+ + A^\dagger_{kl} (E, \vec{R}) I_- + A^\dagger_{kl} (E, \vec{R}) I_+],
$$

with $A(E, \vec{R})$, $A^\dagger(E, \vec{R})$ and $A^\dagger(E, \vec{R})$ denoting $2 \times 2$ matrices and with $c$ given in equation (8). The corresponding matrix elements read

$$
A_{kl} (E, \vec{R}) = \frac{1}{2} \left[ 3 \left( F^{(k;3/2, -1/2)} (\vec{R}) \right)^* F^{(l;3/2, -3/2)} (\vec{R}) + 2 \left( F^{(k;3/2, 1/2)} (\vec{R}) \right)^* F^{(l;3/2, -1/2)} (\vec{R}) + \sqrt{3} \left( F^{(k;3/2, 3/2)} (\vec{R}) \right)^* F^{(l;3/2, 1/2)} (\vec{R}) \right],
$$

$$
A^\dagger_{kl} (E, \vec{R}) = \frac{1}{2} \left[ 3 \left( F^{(k;3/2, -3/2)} (\vec{R}) \right)^* F^{(l;3/2, -1/2)} (\vec{R}) - \left( F^{(k;3/2, -1/2)} (\vec{R}) \right)^* F^{(l;3/2, -1/2)} (\vec{R}) + \left( F^{(k;3/2, 1/2)} (\vec{R}) \right)^* F^{(l;3/2, 1/2)} (\vec{R}) + 3 \left( F^{(k;3/2, 3/2)} (\vec{R}) \right)^* F^{(l;3/2, 3/2)} (\vec{R}) \right],
$$

where the electric field dependence of the envelope functions is omitted for brevity.

For the given dot size, the hole spin interacts with typically $N \approx 10^3$–$10^5$ nuclear spins at positions $\vec{R}_i$ ($i = 1, \ldots, N$). The full interaction Hamiltonian thus reads (with nuclear spin index $i$)

$$
H_{\text{nuc}} = \sum_i H_{1i}^\dagger
$$

$$
= \sum_i c_i \left[ (A(E, \vec{R}_i) + A^\dagger(E, \vec{R}_i)) I_+^i + i[A(E, \vec{R}_i) - A^\dagger(E, \vec{R}_i)] I_-^i + A^\dagger(E, \vec{R}_i) I_+^i \right].
$$

(B.2)

It can be cast into a pseudo-spin-$\frac{1}{2}$ form, where the hole interacts with an effective nuclear magnetic field $\vec{B}_n$, i.e. $H_{\text{nuc}} = \frac{\mu_B}{2} \vec{\sigma} \cdot \vec{B}_n$. Contributions proportional to the identity operator of the pseudo-spin-$\frac{1}{2}$ space do not change the dynamics and have been omitted. The $k$th component of $\vec{B}_n$ is calculated by projecting equation (B.2) onto the Pauli matrix $\sigma_k$ ($k \in \{x, y, z\}$),

$$
(\vec{B}_n)_k = \frac{1}{\mu_B} \text{tr} \{ \sigma_k H_{\text{nuc}} \} \equiv \frac{1}{\mu_B} \sum_i c_i \left[ g_n^{kx}(E, \vec{R}_i) I_+^i + g_n^{ky}(E, \vec{R}_i) I_-^i + g_n^{kz}(E, \vec{R}_i) I_+^i \right],
$$

(B.3)

with

$$
g_n^{kx}(E, \vec{R}_i) \equiv 2 \text{Re} [\text{tr} \{ \sigma_k A(E, \vec{R}_i) \}]
$$

$$
g_n^{ky}(E, \vec{R}_i) \equiv -2 \text{Im} [\text{tr} \{ \sigma_k A(E, \vec{R}_i) \}],
$$

$$
g_n^{kz}(E, \vec{R}_i) \equiv \text{tr} \{ \sigma_k A^\dagger(E, \vec{R}_i) \}.
$$
As noted in section 2.1, we employ a quasi-static approximation for the dynamics of the nuclear spins. We further assume that the spins are uncorrelated, e.g. $\langle I_z^i I_z^m \rangle = 0$ for $i \neq m$, and that only a single nuclear spin species with spin $I_z$ is present. The ‘infinite-temperature’ density matrix of the nuclear spin ensemble reads $\rho_{\text{nuc}} = \frac{1}{2} (I + 1)^{-1}$. Hence, the mean values $\langle I_z^i \rangle$, $\langle I_y^i \rangle$, and $\langle I_z^i \rangle$ vanish and the variances of the nuclear spin components are $\langle I_z^i I_z^i \rangle = \langle I_y^i I_y^i \rangle = \langle I_z^i I_z^i \rangle = I (I + 1)/3$. Furthermore, we can set $c_i = c$. The variances thus read

$$\Delta_k = \{ B_n^k B_n^k \} = \left( \frac{c}{\mu_B} \right)^2 \frac{I (I + 1)}{3} \sum_i \left[ \left\{ g_n^{kx} (E, \vec{R}) \right\}^2 + \left\{ g_n^{ky} (E, \vec{R}) \right\}^2 + \left\{ g_n^{kz} (E, \vec{R}) \right\}^2 \right].$$  \hspace{1cm} (B.4)

The sum in equation (B.4) is performed by a spatial sampling (10⁴ points) of the lh and hh envelope functions. The value of the ratio of the variances with respect to $\Delta_z$ is $\Delta_z/\Delta_x \approx \Delta_y/\Delta_z \approx 0.12$. We then calculate $\Delta_z$ and $\Delta_x$ by setting $\Delta_x = 0.1 \text{ mT}$ (this value corresponds to the experimentally determined lower bound of the hole dephasing time, $T_{2h}^z \approx 100 \text{ ns}$, see section 2.1). We note that the effective nuclear magnetic field and the variances depend on the externally applied electric field via the electric-field dependence of the envelope functions. The values for $\Delta_x/\Delta_z$ given here have been calculated for $E = 0 \text{ kV cm}^{-1}$ and $\vec{B} = (0, 0, 10) \text{ mT}$.
