Abstract. Zirconium oxide (ZrO2) has generated wide interest because of its potential in applications such as solid oxide fuel cells, catalysts and optical devices. In these applications, it is important to control the grain size of the material and increase the surface area by introducing porosity with tailored pore size. This paper presents a synthesis route for the preparation of mesoporous zirconia using spin-coating method combined with block copolymer templating evaporation induced self assembly (EISA). The hybrid mesophase was formed by zirconium oxychloride precursor ZrOCl2⋅8H2O and Brij 700 poly-ethylene oxide based block copolymer template C18H37(OCH2CH2). FT-IR and Raman measurements of the hybrid mesophase provided information on the possible intermolecular interactions between the precursor and the copolymer template. The results indicate a weak ion-dipole interaction between the inorganic precursor and the organic template after the solvent evaporation, possibly directly between the zirconium and the oxygen of the poly-ethylene oxide chain. The removal of the organic block copolymer by heat treatment resulted in mesoporous zirconia with pore size of ~4-8 nm and crystalline grain size of ~10-17 nm. The morphology in thin films depended significantly on the solvent quality and the block copolymer concentration. Tailoring the surface morphology and the grain size resulted in super-hydrophilic mesoporous zirconia thin films in contrast to water contact angle of 50° on conventional tetragonal zirconium oxide.

1. Introduction

The first ordered mesoporous silica synthesized by Krest et al in 1992 [1] started a fast progress in the research field of novel porous inorganic oxides. Mesoporous materials having periodically organized porosity are candidates for applications in the field of catalysis, optics, photonics and sensors because of the increased surface area and nanocrystalline structure [2-4].

For the synthesis of mesoporous ordered metal oxides, the combination of self-assembly procedure and inorganic chemistry is essential. Mainly chemical methods such as spray coating, meniscus coating, spin-coating, dip-coating, pulsed laser deposition [5] and electrochemical deposition [6] are used for the preparation of mesoporous metal oxides [7].

Block copolymer templating with the combination of spin-coating or dip-coating offers a well controllable easy tool and allows tailoring the pore size and structure of mesoporous metal oxides [8, 9]. Block polymer templating by using nonionic surfactant can be divided into four main groups: precipitation method, liquid crystal templating, evaporation induced self assembly and nanocasting on previously formed mesoporous materials [8]. Pinnavaia et al. reported the preparation of mesoporous metal oxide using nonionic poly-ethylene oxide based copolymers [10]. The basis of this synthesis route is the precipitation of the metal precursor in oxide/hydroxide form and its H-bonding to the surfactant. The use of Pluronic type large block copolymers with the same method was reported by Zhao et al [11] for the preparation of highly ordered mesoporous silica. The other commonly used method is evaporation induced self assembly (EISA). The name derives from the preparation process
where from a relatively dilute solution a highly ordered hybrid mesophase (this phase contains both 
the organic and inorganic substances before calcination) can be induced by the solvent evaporation.

Periodically ordered mesoporous zirconia thin films and bulk oxides were prepared by EISA block 
copolymer templating method [12-17]. In these thin films the hexagonally ordered structure tends to 
orient in the plane of the substrate mostly due to electrostatic, van der Waals or 
hydrophobic/hydrophilic attractions between the substrate and the surfactant [18].

The interaction of the inorganic precursors with the organic template in the hybrid mesophase was 
not discussed in detail previously, although the structure of the mesoporous oxide strongly depends on 
such interactions. This article reports on the characterization of the hybrid mesophase formed by 
ZrOCl$_2$$\cdot$8H$_2$O and Brij 700 by FT-IR and Raman spectroscopic methods and presents the evidence for 
the possible intermolecular interactions between the two. In addition, super-hydrophilic mesoporous 
zirconium dioxide thin films will be shown to be formed after the calcination of the hybrid 
mesophase.

2. Experimental methods

Poly-ethylene oxide based block copolymer Brij 700 (C$_{18}$H$_{37}$(OCH$_2$CH$_2$)$_{100}$OH) was purchased from 
Aldrich with the average molecular weight of 4670 g mol$^{-1}$. Zirconium salt (oxychloride) was used as 
inorganic precursor. Reagent grade Zirconium(IV) oxychloride octahydrate was obtained from 
Riedel-de Haën. Ethanol and deionized water mixture was used for the preparation of the solutions in 
the 100-40 volume % ethanol.

The solutions for thin films were prepared by dissolving 0.2-50 mg ml$^{-1}$ polymer in ethanol or 
ethanol-water mixture. The zirconium salt concentration was varied between 0.1-0.25 M in the 
solution. The solutions were aged for 0-2 weeks before the samples were prepared by spin coating. 
The thin layers were spin coated on silica or glass substrates at room temperature, 40-60 % relative 
humidity, rotation speed of 2000 rpm for 120 s using Specialty coating system, INC. spin coater. 
The calcination temperatures were chosen based on the analysis of the thermogravimetric data 
recorded with Seiko SSC/5200 DTA/TG instrument coupled with Mass Spectrometer Pfeiffer 
ThermoStar$^{TM}$ GSD 301 T. The DTA/TG curves were taken in air from 25 °C to 900 °C with the 
heating rate of 10 °C min$^{-1}$. The as prepared and calcined films were characterized using NT-MDT 
Solver P47 atomic force microscope in tapping mode. The X-ray diffraction measurements were 
conducted by Hubert G9670 powder diffraction equipment with germanium monochromator and 
CuK$_{\alpha}$ radiation. The contact angles of the calcined samples were determined by home made set up 
using Digital video camera MDS 100. The 4000–400 cm$^{-1}$ region of the FT-IR spectra was taken on 
the hybrid mesophase and the precursors as KBr discs using a Jasco FT/IR-600 Plus Spectrometer. 
The Raman spectra were measured with Bruker RFS 100/S FT-Raman spectrometer in the range of 
3600–50 cm$^{-1}$ using Nd: YAG-Laser at 1064 nm wavelength (200 mW).

3. Results and discussion

FT-IR and Raman Spectroscopy were done to determine the interaction at molecular level in the 
hybrid mesophase which is critical in understanding the formation mechanism of mesoporous 
zirconium oxide.

First, organic Brij 700 was dissolved in pure ethanol and then ZrOCl$_2$$\cdot$8H$_2$O was added to the 
solution. Following the dissolution of the inorganic salt, 0-40 volume % water was introduced to the 
system. The solvent was then evaporated to form the hybrid mesophase. The same preparation steps 
were repeated for control samples which consisted only ZrOCl$_2$$\cdot$8H$_2$O or Brij 700.

FT-IR and Raman data of control samples were compared with that of the hybrid mesophase. Figure 1(a) represents two characteristic FT-IR spectra of the hybrid mesophase and Brij 700 after 
solvent evaporation in the range of 1400-700 cm$^{-1}$. The solvent was found not to affect the structure of 
the crystalline Brij 700. The characteristic bands were observed at the same positions as previously 
reported [19]. In accordance with the FT-IR results, the XRD measurements (Figure 2(a)) showed the 
characteristic peaks of Brij 700 and the crystalline phases in the hybrid mesophase were identified as 
the mixture of mainly ZrOCl$_2$$\cdot$8H$_2$O and Brij 700. In the infrared spectrum, the hybrid mesophase 
shows all the bands characteristic for Brij 700 and ZrOCl$_2$ with very small to significant shifts with 
respect to the pure compounds.
The C-O-C vibrations at 1145, 1108 and 1069 cm\(^{-1}\) are broadened while the bands at 962 and 944 cm\(^{-1}\) in Brij 700 shifted to 945 and 912 cm\(^{-1}\) in the hybrid mesophase. This indicates that the C-O-C bond is weakened in the poly-ethylene oxide chain due to the interaction with the inorganic ZrOCl\(_2\). The analysis of the Zr-O bands with and without Brij 700 can provide further information to understand whether Zr interacts directly with the organic compound in the hybrid mesophase. Therefore, the two Zr-O Raman bands of ZrOCl\(_2\) between 350-650 cm\(^{-1}\) were compared with those of the hybrid mesophase. The characteristic band in the Raman spectrum (not shown) in solid ZrOCl\(_2\) at 575 cm\(^{-1}\) shifted to 592 cm\(^{-1}\) while the one at 459 cm\(^{-1}\) broadened in the dried hybrid mesophase. FT-IR results together with the Raman measurements thus indicated a direct interaction between Zr and the O of the poly-ethylene oxide chain. This is possible by the replacement of the water molecules in ZrOCl\(_2\)\(\cdot\)8H\(_2\)O and the formation of an ion-dipole interaction.

The decomposition of the Brij 700 in the hybrid mesophase and the oxide formation was followed by differential thermal analysis/thermogravimetric measurements (DTA/TG) coupled with mass spectroscopy. Figure 1(b) represents typical thermogravimetric and differential thermal analysis curves of the hybrid mesophase. All measurements showed three endothermic peaks in the DTA curves at the onset temperature of 50, 70 and 130 °C. The first peak is due to the melting of the polymer and did not correspond to any significant changes in the thermogravimetric data. The second and third peaks correspond to ~35% mass loss which is the removal of the water from ZrOCl\(_2\)\(\cdot\)8H\(_2\)O and from those absorbed into the mesophase in ambient atmosphere. This was confirmed by mass spectroscopic analysis of the gas phase as well. In addition to the endothermic peaks, two exothermic peaks appeared on the DTA curve when the temperature was further increased. The first exothermic peak starts at around 280 °C and corresponds to the decomposition of the Brij 700 to CO and CO\(_2\) with ~30% mass loss. The small shoulder on this peak indicates heterogeneous polymer structures. The second exothermic peak starts at around 480 °C and can be attributed to the change of the amorphous structure to crystalline zirconium oxide. Based on these results, the calcination temperature of the hybrid mesophase was chosen to be 450 °C. The layers were heated with the ramp of 1°C min\(^{-1}\) to 450 °C, kept at this temperature for 4 hours and then cooled at the same rate to room temperature. The final product was identified after complete removal of the Brij 700 by XRD data of Figure 2(a) as tetragonal ZrO\(_2\) with the crystalline grain size of ~10-17 nm. When the water content was low in the solvent mixture, very small amount of monoclinic ZrO\(_2\) formed in addition to the tetragonal major phase.

Besides the relative humidity, the percentage of water in the solvent mixture and the block copolymer concentration in the solution were the main factors which mostly influenced the pore structure of zirconium oxide. These factors were altered and optimized for the formation of mesoporous zirconium oxide. Figure 2(b) represents one characteristic AFM image of the resulting mesoporous thin film having a thickness of 150 nm. The sample was prepared from 20 mg ml\(^{-1}\) Brij 700, 0.25 M ZrOCl\(_2\)\(\cdot\)8H\(_2\)O and the mixture of 80% ethanol 20% water solution and was calcined. The ordered 2D hexagonal structure oriented in the plane of the substrate [12, 18]. In Figure 2(b), this ordered structure appears as stripes with the diameter of ~4-8 nm directed from lower right to upper left corner.
Contact angle of water on conventional chemically stabilized tetragonal ZrO$_2$ is 50$^\circ$ [20]. The successful introduction of mesoporosity decreased the water contact angle to 5$^\circ$ due to well-known surface roughness effect and resulted in super-hydrophilic films [20].

In summary, mesoporous tetragonal zirconium dioxide was successfully synthesized with ordered structure. The crystalline grain size of the layers was $\sim$10-17 nm while the pore size was $\sim$4-8 nm. Based on the FT-IR and Raman measurements, a direct interaction between Zr and the O of the polyethylene oxide chain was concluded in the hybrid mesophase. The calcination of the mesophase at 450 $^\circ$C resulted in super-hydrophilic ZrO$_2$ thin films with a water contact angle of 5$^\circ$.
