Abstract

Millimeter observations of CO gas in planetesimal belts show a high detection rate around A stars, but few detections for later type stars. We present the first CO detection in a planetesimal belt around an M star, TWA 7. The optically thin CO ($J = 3$–2) emission is colocated with previously identified dust emission from the belt, and the emission velocity structure is consistent with Keplerian rotation around the central star. The detected CO is not well shielded against photodissociation, and must thus be continuously replenished by gas release from exocomets within the belt. We analyze in detail the process of exocometary gas release and destruction around young M dwarfs and how this process compares to earlier type stars. Taking these differences into account, we find that CO generation through exocometary gas release naturally explains the increasing CO detection rates with stellar luminosity, mostly because the CO production rate from the collisional cascade is directly proportional to stellar luminosity. More luminous stars will therefore on average host more massive (and hence more easily detectable) exocometary CO disks, leading to the higher detection rates observed. The current CO detection rates are consistent with a ubiquitous release of exocometary gas in planetesimal belts, independent of spectral type.

Key words: circumstellar matter – comets: general – molecular processes – planetary systems – stars: individual (TWA 7) – submillimeter: planetary systems

1. Introduction

Planetesimal belts, also known as debris disks, are extrasolar Kuiper and asteroid belt analogues, detected around a significant fraction of nearby, main-sequence solar-type (FGK) and A stars (for a review see, e.g., Hughes et al. 2018; Wyatt 2018). Detectable belts are collision-dominated environments, where the mass of the observed dust and larger planetesimals in a so-called *collisional cascade* depletes over time (as observed, e.g., Wyatt et al. 2007; Holland et al. 2017; Sibthorpe et al. 2018). To date, 19 of these belts have been detected in one or several gas tracers. Detection of gas in planetesimal belts has the potential to inform us about exocometary compositions (Matrà et al. 2017b, 2018b), particularly during the ∼10–100 Myr period when terrestrial planet formation is still ongoing, and volatile delivery events through exocomets may be commonplace (e.g., Morbidelli et al. 2012).

CO dominates the number of detections (17/19), in part thanks to the unprecedented sensitivity of the Atacama Large Millimeter/submillimeter Array (ALMA). For many systems, it remains debated whether the gas is primordial or secondary in origin, where primordial gas is a long-lived remnant of the protoplanetary disk (Kóspál et al. 2013), whereas secondary gas is second generation like the dust, produced by exocometary gas release (e.g., Zuckerman & Song 2012; Matrà et al. 2015).

In five of these belts, the CO masses and line opacities have been well established, and the resulting low CO masses and optically thin CO lines can only be explained by a second generation origin (Dent et al. 2014; Marino et al. 2016, 2017; Matrà et al. 2017a, 2017b; Booth et al. 2019). The origin of gas

for the more massive CO-bearing belts remains unconfirmed, but there are indicators suggesting an absence or a significant depletion of H_2, which would point toward a secondary origin for them, too (e.g., Higuchi et al. 2017; Hughes et al. 2017).

A puzzling outcome of the first global analysis of the CO detections is a significantly higher occurrence rate of CO in belts around A stars compared to lower luminosity stars (Moór et al. 2017). Indeed, no detection has been reported to date around stars of types later than F, which constitute the overwhelming majority of stars in our Galaxy.

In this work, we aim to understand how the presence of CO gas in a planetesimal belt is affected by its stellar host, and explain the origin of the decreasing CO occurrence rates around stars of decreasing stellar luminosity. We do so by presenting the first ALMA detection of CO in a planetesimal belt around an M3-type (Ducourant et al. 2014) dwarf, TWA 7. This nearby star (34.0 pc, Gaia Collaboration et al. 2018) is part of the TWA association (Webb et al. 1999), setting its age at ∼10 Myr (Bell et al. 2015). Its infrared excess was detected by *Spitzer* (Low et al. 2005) and confirmed by *Herschel* (Riviere-Marichalar et al. 2013). The first scattered light image of the outer regions of the belt was obtained by the *Hubble Space Telescope* (*HST*; Choquet et al. 2016), and more recent SPHERE data resolve the belt's inner regions showing broad emission from a face-on ring extending from ∼20 to at least ≳70 au (Olofsson et al. 2018). Unresolved submillimeter emission was detected by the James Clerk Maxwell Telescope (JCMT; Matthews et al. 2007). However, ALMA observations recently showed that the JCMT flux is actually dominated by an unrelated source ∼6″.6 offset from the star (likely a submillimeter galaxy), although the fainter-than-expected belt is also detected and marginally resolved (Bayo et al. 2018).

Here we analyze the CO cube obtained as part of the same ALMA data set as described in Bayo et al. (2018). In Section 2,

[4] Submillimeter Array (SMA) Fellow.

we summarize the interferometric observations, including their calibration and imaging. Section 3 presents our analysis of the CO data and a derivation of physical parameters from measured quantities. In Section 4, we demonstrate the exocometary origin of the gas, and examine how of the exocometary release process differs around M stars compared to more luminous stars. Finally, we discuss the origin of the stellar luminosity dependence of the CO detection rates in the context of exocometary gas release. We conclude by summarizing our findings in Section 5.

2. Observations

TWA 7 was observed by ALMA in Band 7 using the 12 m array in 2016. Three observations were obtained, one with 42 antennas in a compact configuration pointed at coordinates R. A. $10^h42^m29\overset{s}{.}904$, decl. $-33^d40^m17\overset{s}{.}098$, and two with 36 antennas in a more extended configuration pointed at coordinates R.A. $10^h42^m30\overset{s}{.}413$, decl. $-33^d40^m16\overset{s}{.}700$, altogether spanning baselines from 15.1 m to 3.1 km. Further details of the observations can be obtained in Bayo et al. (2018). Standard calibrations were applied to each data set using the ALMA pipeline in CASA v5.1.0. A CO visibility data set was produced covering $\sim$1200, 244.141 kHz wide channels around the transition frequency (345.796 GHz), with continuum emission subtracted from it using the *uvcontsub* CASA task. For continuum imaging, we considered all 6.9 GHz covered by the four spectral windows of each of the observations.

For both CO and continuum, calibrated visibilities from the different observations and configurations were imaged both separately and together using the *tclean* task within CASA, in mosaic mode with multiscale deconvolution. To improve sensitivity to extended emission originating from the belt, we use natural weighting and further apply a $2''$ u–v taper to the visibilities prior to imaging. The final CO data cube reaches an rms sensitivity of 7 mJy/beam in a 244.141 kHz channel (corresponding to 0.21 km s^{-1} at 345.796 GHz) for a synthesized beam size of $1\overset{''}{.}8 \times 1\overset{''}{.}7$ (62×58 au at the distance of the star from Earth). The continuum image has an rms noise level of 0.07 mJy/beam for the same synthesized beam size.

3. Results and Analysis

3.1. Spectrospatial Filtering: CO J = 3–2 Detection

No strong emission is observed after a quick inspection of the CO data cube around the radial velocity of the star (11.9 ± 0.4 km s^{-1} in the heliocentric frame; Gagné et al. 2017). Following the method of Matrà et al. (2015, 2017b), we apply a spectrospatial filtering technique in order to boost the signal-to-noise ratio (S/N) and achieve maximum sensitivity (Figure 1). First, we simply spatially integrate over the region within $\sim 3\overset{''}{.}5$ from the star where continuum emission from the belt is detected above the 2σ level. This produces the red spectrum, where a hint of a Keplerian double-peaked profile already emerges from the noise around the expected stellar velocity. To test whether this signal truly originates from circumstellar gas, we then assume that CO orbits with the Keplerian velocity field expected around a star of $0.55 M_\odot$ (Neuhäuser et al. 2000), for a disk with an inclination ($13°$) and position angle (PA, $91°$) as derived from high resolution dust imaging in the near-infrared (near-IR; Olofsson et al. 2018). The unknown rotation direction leads to two possible velocity

Figure 1. CO $J = 3$–2 spectra of the belt around TWA 7, spatially integrated over the region where continuum is detected at the $\sim 2\sigma$ level. The top (red) spectrum is obtained without any spectral filtering, whereas the center and bottom spectra are obtained by shifting the 1D spectra at each pixel location by the negative of their expected Keplerian velocity at that location. Two possible signs of the velocity are possible, depending on whether the east side of the belt is moving away or toward us, leading respectively to the green and blue spectra. The gray region indicates the $\pm 1\sigma$ confidence interval for the stellar radial velocity (Gagné et al. 2017). The green shaded region represents the best-fit Gaussian profile to the spectrospatially filtered emission, used to quantify the integrated line flux.

fields, with the east side of the disk moving away from Earth or toward Earth.

For each of the two possible velocity fields, we assign each pixel a given expected radial velocity and shift the 1D spectrum in that pixel along the frequency (velocity) axis, by the negative of its assigned radial velocity. Then, we spatially integrate over the region where continuum emission is detected, to produce the green and blue spectra. We find that the detection is significantly boosted from a peak S/N of 3.7σ to 6.4σ for a Keplerian velocity field where the east side of the disk is moving away from us, whereas no boost is achieved when the sign of the velocity field is inverted.

After shifting the spectra in each pixel of the cube along the velocity axis, we also produce a moment-0 map by spectrally integrating emission over the four channels nearest to the stellar velocity. Then, we extract a radial profile by azimuthally averaging emission in concentric elliptical annuli (accounting for the belt's inclination and PA). This radial profile is shown by the blue shaded region in Figure 2. We find that CO emission is detected out to $\sim$100 au from the star, with a radial profile consistent with that extracted from the continuum images, tracing the dust emission (red shaded region). The present data set does not allow us to resolve the inner hole of the dust belt, found to lie at $\sim$20 au in near-IR observations (Olofsson et al. 2018), while at the same time retaining sensitivity to the extended belt structure. Future, higher sensitivity observations are necessary for a detailed comparison of the radial structure of both large, planetesimal-tracing grains and CO emission.
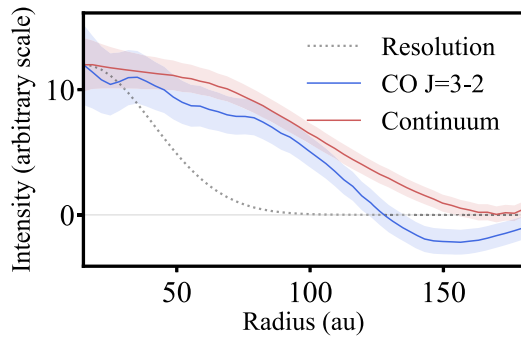

Figure 2. Radial profiles for continuum emission (red line), and for CO $J = 3$–2 emission after the same spectral filtering that led to the green spectrum (blue line). Shaded regions indicate $\pm 1\sigma$ uncertainties, and the dashed line represents the spatial resolution of our observations.

We conclude that (1) CO $J = 3$–2 emission is significantly detected at the radial velocity of TWA 7, at a location consistent with that of the belt of millimeter grains, and (2) its radial velocity field is consistent with circumstellar gas colocated with the dust and in Keplerian rotation around the star, with the east side of the gas disk moving away from Earth.

3.2. CO Mass and Optical Depth Estimate

We measure the integrated CO line flux by fitting a Gaussian to the green, spectrospatially filtered spectrum of Figure 1, obtaining a value of 91 ± 20 mJy km s^{-1} for a centroid radial velocity of 11.75 ± 0.08 km s^{-1}. Uncertainties were calculated from SCIPY's *curve_fit* nonlinear least squares method (Jones et al. 2001). These rely on the input uncertainty on the flux for each channel, which was assumed to be equal to the rms of the spectrum multiplied by a factor of $\sqrt{2.667}$. The latter was introduced to account for the fact that neighboring channels are correlated, and the effective bandwidth of the flux in each channel is 2.667 times the width of that channel.[5] Multiplying the rms by a factor of $\sqrt{2.667}$ then takes care of the fact that while the line is resolved over approximately seven channels, there are really only $\sim 7/2.667 = 2.62$ independent measurements, therefore ensuring that the error on the final parameters is not underestimated. The uncertainty on the line flux included an extra 10% added in quadrature to account for ALMA's flux calibration uncertainty in Band 7.[6]

Assuming optically thin emission, we use the non-LTE excitation code of Matrà et al. (2015, 2018b) to find that the best-fit line flux corresponds to CO masses in the range of $(0.8$–$80) \times 10^{-6}\,M_{\oplus}$, where the range comes from the two limiting regimes of molecular excitation, at high collider density (collision-dominated regime, or LTE) and low collider density (radiation-dominated regime). Note that in order to calculate the effect of UV and IR pumping on CO excitation, we adopt the interstellar radiation field (ISRF) of Draine (1978) and a PHOENIX stellar photospheric model fitted to observations of TWA 7 with synthetic photometry ($T_{\rm eff} = 3394$ K, log $(g) = 3.7$, $[M/H] = 0.0$), and scaled to a distance of 60 au from the star. If instead we were to scale the model to the inner edge of the belt, or if the model took into account excess UV chromospheric emission (see Section 4.1), UV pumping would

[6] https://almascience.nrao.edu/documents-and-tools/cycle6/alma-technical-handbook

be stronger and act to reduce the upper limit of the range of masses given above.

We then verify the optically thin assumption by assuming that CO emission is colocated with continuum emission (which is informed by the radial profiles in Figure 2) and that this is colocated with dust emission seen at higher resolution at optical wavelengths (Olofsson et al. 2018). Specifically, we assume the disk to extend between 20 and 100 au, and to have a constant surface brightness. For simplicity, we assume the belt to be perfectly face-on, where this introduces only a $\sim 3\%$ uncertainty in the length of the column along the line of sight to Earth, given the known belt inclination of $\sim 13°$ (Olofsson et al. 2018). Then, the CO mass derived above corresponds to an average column density between ~ 0.15 and 15×10^{14} molecules cm^{-2}, which can be used to derive a maximum optical depth of $\tau < 0.27$ (using Equation (3) in Matrà et al. 2017a, and the full range of excitation conditions used to derive CO masses). This confirms the validity of our optically thin emission assumption and of our CO mass estimate of $(0.8$–$80) \times 10^{-6}\,M_{\oplus}$.

4. Discussion

4.1. CO Photodissociation around Young M Dwarfs due to Chromospheric Far-UV Emission

The CO gas detected is continuously affected by the impinging stellar and interstellar UV radiation field, which in the ~ 900–1100 Å wavelength range leads to photodissociation (e.g., Visser et al. 2009). Contrary to the conclusion one would draw from a simple comparison of stellar photospheric models, the photodissociation-driving far-UV (FUV) intensity of young M dwarfs is not negligible compared to, for example, coeval A stars. This is because FUV emission is dominated by emission lines originating from the chromosphere and/or transition region of the star, with only a negligible contribution from the stellar photosphere (Linsky 2017). These lines are strongest around active stars, such as young M dwarfs, but can also be present and dominate the FUV continuum around more massive stars such as β Pictoris (Deleuil et al. 2001; Bouret et al. 2002). Then, photodissociation of exocometary CO across stars of different luminosities does not simply scale with the stellar effective temperature, but will strongly depend on the details of the stars' chromospheric emission and FUV spectra. Since TWA 7 has not been observed in the ~ 900–1100 Å range, we use the spectrum of the similar, young M dwarf AU Mic and rescale its intensities by the ratio of FUV luminosities between 1250 and 1700 Å, observed for both stars with the *HST*. In the latter UV range, TWA 7 was found to be more luminous than AU Mic by a factor of ~ 1.5 (Yang et al. 2012).

Since CO photodissociation is a line process, it is sensitive to the presence of stellar chromospheric lines that overlap with electronic CO transitions leading to predissociative excited states. In the case of β Pic, the broad C III chromospheric line at 977.02 Å is by far the strongest component of the FUV spectrum, and it overlaps with a predissociative absorption band of CO at 977.40 Å (see Band 26 in Table 1 of Visser et al. 2009). It therefore dominates the stellar CO photodissociation (see Figure 3 of Matrà et al. 2018b). The same line carries most of the FUV flux of the coeval (~ 23 Myr old) M dwarf AU Mic (Redfield et al. 2002). The chromospheric line and the CO line do not overlap perfectly, however, and because chromospheric lines are relatively narrow in M dwarfs, only some of the

emission contributes to CO photodissociation. Even so, this line is the likely dominant contributor to stellar CO photodissociation around AU Mic, and by inference around TWA 7. We therefore use the C III stellar line intensities as measured in the FUSE spectra at 977.40 Å as a proxy for the strength of CO-photodissociating stellar radiation. For AU Mic, we use the quiescent flux of $\sim 0.5 \times 10^{-13}$ erg cm^{-2} s^{-1} Å^{-1}, but note that this increased to $\sim 8.5 \times 10^{-13}$ erg cm^{-2} s^{-1} Å^{-1} during an observed flare (see Figure 17 of Redfield et al. 2002).

Combining the 977.40 Å flux of AU Mic with the $\sim 2 \times 10^{-13}$ erg cm^{-2} s^{-1} Å^{-1} measurement of β Pic (Bouret et al. 2002), and scaling to TWA 7 accounting for the respective distances from Earth, we find that the CO-photodissociating radiation of M star TWA 7 is at least $\sim 6\%$ that of A star β Pic. Given that β Pic's unshielded CO photodissociation timescale at 85 au is 70 yr (Cataldi et al. 2018), TWA 7's star-driven CO photodissociation timescale at 60 au will be 580 yr, which is longer than the photodissociation timescale driven by the interstellar radiation field (ISRF) alone (120 yr, e.g., Heays et al. 2017). Combining the (quiescent) stellar and ISRF, we conclude that the CO unshielded photodissociation timescale around TWA 7 is 99 yr at 60 au, varying from 55 yr at 25 au to 112 yr at 100 au. If flares were taken into account, this timescale could be even shorter.

4.2. Exocometary Origin for TWA 7 CO

The low, optically thin levels of CO detected around the ~ 10 Myr old star TWA 7 supports a picture where the gas is of secondary origin, i.e., produced within a destructive collisional cascade. But can we rule out that the CO is primordial or, in other words, left over from a depleted, old protoplanetary disk? Unshielded CO will be photodissociated in ~ 100 yr (Section 4.1), but can self-shielding or shielding by other gas species have prolonged its lifetime and allow it to survive since the protoplanetary phase of evolution?

A CO molecule lying in the midplane of the disk will see a CO column density of at most $\sim 7.5 \times 10^{14}$ cm^{-2} above the midplane (half of the maximum value derived in Section 3.2). Using the self-shielding factors of Visser et al. (2009), CO can only prolong its own lifetime by a factor 2.5, corresponding to a lifetime of 250 yr (see their Table 7). If the disk was primordial in origin, we may expect large amounts of H$_2$ to be present. Conservatively assuming CO to be depleted with respect to H$_2$ compared to interstellar abundances, with a CO/H$_2$ ratio of 10^{-6} (as in the coeval TW Hya protoplanetary disk; Favre et al. 2013), the photodissociation lifetime is only prolonged by another factor of 4 to 1000 yr, and less so if the CO/H$_2$ ratio was interstellar. Since this is much shorter than the age of the system, we conclude that primordial CO, originating in the protoplanetary disk, is not responsible for the observed CO in the TWA 7 belt (unless the protoplanetary disk dispersed within the last 1000 yr, which is very unlikely). The observed CO gas most likely originates in the collisional cascade that also produces the observed dust, i.e., it has an exocometary origin.

4.3. The Exocometary Gas Release Process around M Dwarfs

TWA 7 joins a group of five other planetesimal belt systems with CO gas confirmed to be of exocometary origin, comprising β Pictoris (Matrà et al. 2017a), HD181327 (Marino et al. 2016), η Corvi (Marino et al. 2017), Fomalhaut (Matrà et al. 2017b), and HD95086 (Booth et al. 2019). In these disks, the measured CO gas mass can be used to probe the volatile composition of exocomets. This is done by considering a model where the gas is continuously released as part of the collisional cascade, which also produces the observed dust (e.g., Zuckerman & Song 2012; Matrà et al. 2015). The CO release is assumed to be at steady state, with the release rate being equal to the photodissociation rate. The CO release rate is simply the rate at which solid mass is lost from the collisional cascade, combined with the CO ($+CO_2$) exocometary mass fraction. This allows the exocometary mass fraction to be derived from simple dust, CO, and host star observables (Equation (2) of Matrà et al. 2017b).

4.3.1. Mass-loss Rate of Small Grains

In the argument above, extracting the exocometary mass fraction requires knowledge of the mass-loss rate of the smallest grains, which for typically observed belts occurs by radiation pressure from the central star. However, TWA 7 is an M dwarf, which means that radiation pressure is unable to eject and remove the smallest grains from the system, and stellar winds play a dominant role (e.g., Plavchan et al. 2005; Augereau & Beust 2006). Stellar winds create outward ram pressure on the grains, an effect analogous to radiation pressure, as well as corpuscular drag causing the grains to lose angular momentum and drift inward, analogously to P–R drag. Strubbe & Chiang (2006) considered these effects in detail, and showed that belts where the mass loss is dominated by corpuscular wind drag should present an inner hole that is filled with small grains spiralling inward, and a steep outer slope of the surface density distribution. These are not observed in SPHERE images of TWA 7, tracing the smallest grains (Olofsson et al. 2018). We therefore postulate that small grain removal from the TWA 7 belt is dominated by outward stellar wind pressure.

In a steady-state cascade, the mass-loss rate of the smallest, blow-out grains is the same as the total mass of these smallest grains multiplied by the collision rate of grains just above this size, which can be calculated (see Matrà et al. 2017b for details). The minimum grain size influences the total mass and area available for collisions, thus impacting the calculated mass-loss rate of blow-out grains. Therefore, the difference between stellar winds for M dwarfs and radiation pressure for more massive stars enters the calculation of the mass-loss rate only by setting the size of the smallest grains, $D_{\min}$. For stellar wind dominated removal, this reads as (Augereau & Beust 2006)

$$D_{\min} = 2.8 \times 10^{11} \frac{\dot{M}_\star v_{\rm sw} C_{\rm D}}{M_\star \rho}, \tag{1}$$

where $D_{\min}$ is in μm, $\dot{M}_\star$ is the mass-loss rate of the star due to the wind (in $M_\odot$ yr^{-1}), $v_{\rm sw}$ is the wind velocity (in km s^{-1}), $C_{\rm D}$ is the drag coefficient of the free molecular flow, $M_\star$ is the stellar mass (in $M_\odot$), and ρ is the density of the grains (in kg m^{-3}).

Unfortunately, there is no measurement of these M-dwarf wind properties. However, given that our calculation of the mass-loss rate of grains only relies on the minimum grain size the wind produces, we can simply use the $D_{\min}$ value of ~ 0.16 μm constrained from a spectral energy distribution (SED) fitting (for astrosilicate grains with $\rho = 3500$ kg m^{-3},

and an assumed Dohnanyi 1969 size distribution; Bayo et al. 2018). Assuming that these grains dominate the observed IR luminosity, and taking TWA 7's stellar mass of $0.51\,M_\odot$, fractional luminosity of 1.7×10^{-3}, and approximate belt radius of $\sim$60 au with width of $\sim$80 au, we obtain a mass of the smallest grains of $1 \times 10^{-4}\,M_\oplus$ and a collisional timescale of 3×10^4 yr (Equations (16) and (20) in Appendix B of Matrà et al. 2017b). Together, this implies a mass-loss rate of small grains from the collisional cascade of $0.003\,M_\oplus\,\mathrm{Myr}^{-1}$.

4.3.2. Estimate of Exocometary Compositions in TWA 7

Given a measured CO mass in the range of $(0.8$–$80) \times 10^{-6}\,M_\oplus$, and taking the unshielded photodissociation timescale of 100 yr at 60 au, we estimate a mass-loss rate of CO gas through photodissociation of 0.008–$0.8\,M_\oplus\,\mathrm{Myr}^{-1}$. In steady state, this will correspond to the mass-loss rate $\dot{M}_{\mathrm{CO(+CO_2)}}$ of $\mathrm{CO(+CO_2)}$ from the ice. Adding this to the mass-loss rate $\dot{M}_{D_{\min}}$ of grains from the bottom of the collisional cascade of $0.003\,M_\oplus\,\mathrm{Myr}^{-1}$ (Section 4.3.1), and assuming that the release rate of volatiles other than CO and its potential parent species CO_2 (which are yet to be detected in a gaseous form within exocometary belts; e.g., Matrà et al. 2018b) is negligible, we obtain the total rate of mass loss through the collisional cascade $\dot{M} = \dot{M}_{\mathrm{CO(+CO_2)}} + \dot{M}_{D_{\min}}$. As long as all $\mathrm{CO(+CO_2)}$ ice is lost (through, e.g., sublimation and/or photodesorption; see the discussion in Matrà et al. 2017b) by the time a large body is ground down to blow-out size grains, then $\dot{M}_{\mathrm{CO(+CO_2)}} = f_{\mathrm{CO+CO_2}}\dot{M}$, where $f_{\mathrm{CO+CO_2}}$ is the $\mathrm{CO(+CO_2)}$ mass fraction in TWA 7's exocomets. This reasoning leads to Equation (1) in Matrà et al. (2017b) and allow us to derive a $\mathrm{CO(+CO_2)}$ mass fraction of $f_{\mathrm{CO+CO_2}} \geqslant 70\%$ for exocomets around TWA 7.

This value is high compared to the few to few tens of percent observed for other stars hosting exocometary CO (Section 4.3) as well as solar system comets (Matrà et al. 2017b), and would imply icy bodies almost entirely composed of CO and CO_2 ice. It is possible that exocomets around M dwarfs do have a distinct composition. However, our estimate is subject to uncertain assumptions that need to be observationally tested. First, the observational estimate of the minimum grain size from the SED could vary by as much as an order of magnitude by changing the assumed grain composition. Second, the photodissociation timescale could vary by a factor of a few from our basic rescaling using the 977.40 Å line flux of AU Mic. This could be due to, for example, observations when the stars were at different activity levels, or if our rescaling does not apply to the chromospheric 977.40 Å C III line. The presence of flares (both in AU Mic and and TWA 7) could also shorten, whereas self-shielding could lengthen the photodissociation timescale, making the derived CO mass fraction respectively larger or smaller.

Finally, shielding by other atoms or molecules could be more important than assumed in our calculations. Although reasonable H_2 abundances cannot reasonably provide sufficient shielding against photodissociating UV light (Section 4.2), atomic carbon produced by CO photodissociation could (e.g., Matrà et al. 2017a). Depending on the true $\mathrm{CO(+CO_2)}$ ice mass fraction in TWA 7's exocomets and on the α viscosity of the gas disk, TWA 7 could be producing C at a fast enough rate for it to shield CO before spreading radially (Kral et al. 2018, e.g., their Figure 18, bottom right). This would prolong the CO survival timescale against photodissociation, potentially

reducing the derived $\mathrm{CO(+CO_2)}$ mass fraction to more commonly observed values. Follow-up ALMA measurements of the C I gas mass and of another CO transition to better constrain the CO gas mass will have the ability to set more stringent constraints on the composition of TWA 7's exocomets.

4.4. On the Stellar Luminosity Dependence and Ubiquity of Exocometary CO Gas Release

There are 17 CO detections in extrasolar planetesimal belts, 6 of which (including TWA 7) are conclusively of exocometary origin. These CO-producing exocometary belts span ages between $\sim$10 Myr and 1–2 Gyr, implying that the presence of gas is not limited to young stars. It is indeed possible that all icy planetesimal belts host exocometary gas at some level, and that the CO outgassing is simply proportional to the mass-loss rate of the collisional cascade.

4.4.1. The Mass of Exocometary Gas Released Depends on the Host Star's Luminosity

This statement has to be reconciled with the dependence of the detection rate of CO in planetesimal belts on stellar luminosity. Moór et al. (2017) reported a very high detection rate of $68.8^{+8.9}_{-13.1}\%$ in belts around A stars with high fractional luminosity ($>5 \times 10^{-4}$). However, they also note that the rate drops significantly to $6.7^{+12.5}_{-2.2}\%$ for belts around the FG stars in their sample. Can exocometary release explain this trend by producing higher CO masses around more luminous stars?

Inverting Equation (2) in Matrà et al. (2017b), the CO mass (in $M_\oplus$) predicted for any given planetesimal belt reads as

$$M_{\mathrm{CO}} = \dot{M}_{D_{\min,\mathrm{rp}}} t_{\mathrm{phd}} \frac{f_{\mathrm{CO+CO_2}}}{1 - f_{\mathrm{CO+CO_2}}}$$
$$= 1.2 \times 10^{-3} R^{1.5} \Delta R^{-1} f^2 L_\star M_\star^{-0.5} t_{\mathrm{phd}} \frac{f_{\mathrm{CO+CO_2}}}{1 - f_{\mathrm{CO+CO_2}}}, \quad (2)$$

where R and ΔR are the radius and width of the belt in au, $L_\star$ and $M_\star$ are the stellar luminosity and mass in $L_\odot$ and $M_\odot$, t_{phd} is in years, f is the fractional luminosity of the belt, $\dot{M}_{D_{\min,\mathrm{rp}}}$ is the mass-loss rate of blow-out grains via radiation pressure, and the resulting CO mass M_{CO} is in $M_\oplus$.

This is for the case where the minimum grain size of the cascade is set by radiation pressure, which will apply for stars of spectral type earlier than M. For M stars, the minimum size is set by stellar winds, which causes the expression above to turn into

$$M_{\mathrm{CO}} = \dot{M}_{D_{\min,\mathrm{sw}}} t_{\mathrm{phd}} \frac{f_{\mathrm{CO+CO_2}}}{1 - f_{\mathrm{CO+CO_2}}}$$
$$= 1.6 \times 10^5 R^{1.5} \Delta R^{-1} f^2 \dot{M}_\star v_{\mathrm{sw}} C_{\mathrm{D}} M_\star^{-0.5} t_{\mathrm{phd}} \frac{f_{\mathrm{CO+CO_2}}}{1 - f_{\mathrm{CO+CO_2}}},$$
$$(3)$$

where $\dot{M}_{D_{\min,\mathrm{sw}}}$ is the mass-loss rate of blow-out grains via stellar winds, $\dot{M}_\star$ is the mass-loss rate of the stellar wind itself (in $M_\odot\,\mathrm{yr}^{-1}$), v_{sw} is the wind velocity (in $\mathrm{km\,s}^{-1}$), and C_{D} is the drag coefficient of the free molecular flow. The main difference between the radiation pressure case (Equation (2)) and the stellar wind case (Equation (3)) is that the stellar luminosity is
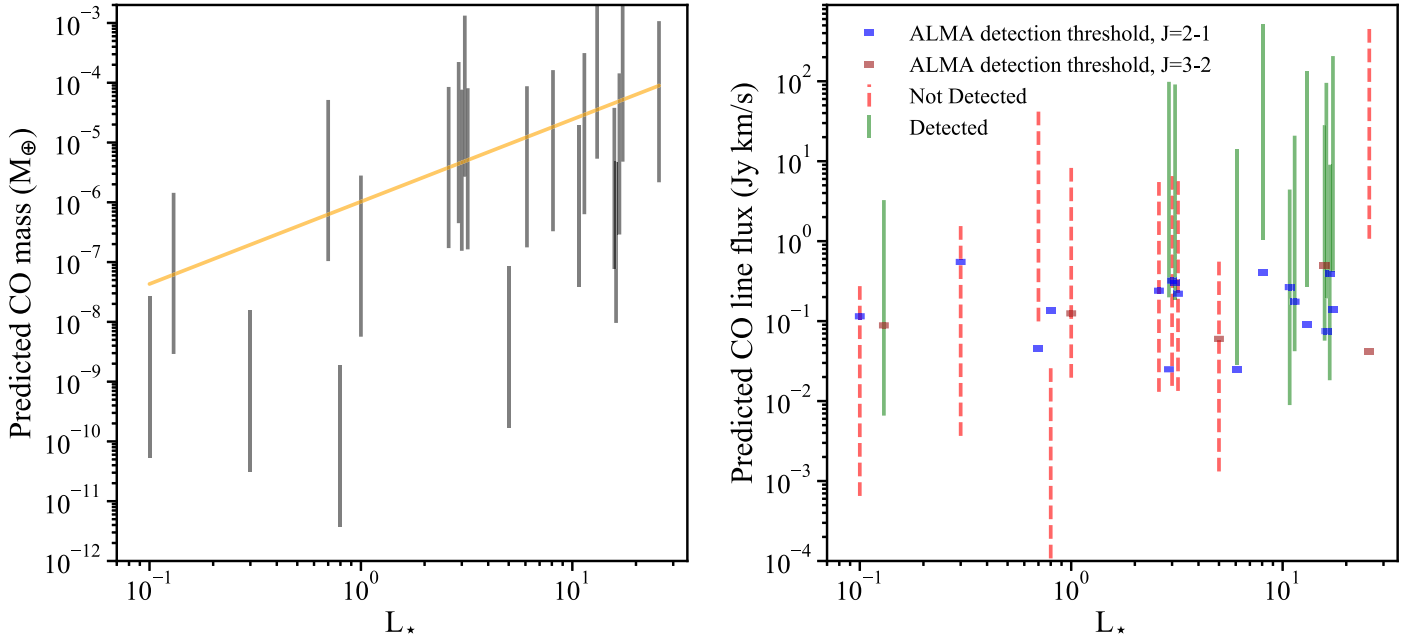

Figure 3. Left: predicted exocometary CO gas mass for belts that have been resolved and searched for CO by ALMA so far, as a function of stellar luminosity, and for a 0.8%–80% range of assumed CO(+CO_2) exocometary ice mass fractions (gray bars). The sample of stellar and belt properties used in the calculation are from this work for TWA 7, from Kennedy et al. (2018) for HR4796A, and from Matrà et al. (2018a) for the remainder of the sample. The orange line is a prediction assuming $R = 73L_\star^{0.19}$ (Matrà et al. 2018a), a constant photodissociation timescale of 120 yr, a CO(+CO_2) mass fraction of 20%, a constant $\Delta R/R = 0.4$, $M_\star = L_\star^{0.25}$, and $f = (1.56 \times 10^{-3})L_\star^{0.2}$. Right: predicted integrated CO line fluxes for the given CO mass ranges in the left panel, given the star's respective distances from Earth and an excitation temperature of 20 K. The green solid bars represent targets with detected CO, whereas the red dashed bars are for targets where CO was not detected. The horizontal bars represent, for each target, the 5σ detection threshold of its actual ALMA observation from the literature. The blue bars are for targets where the $J = 2$–1 transition was observed, and the brown ones are for the $J = 3$–2 transition. In both panels, the exocometary release model predicts increasing masses and fluxes of CO for stars of increasing luminosity. Combined with the detection thresholds, this explains the increasing CO detection rate as a function of stellar luminosity reported by Moór et al. (2017).

substituted by the product of the stellar wind mass-loss rate, its velocity, and the drag coefficient C_D.

We immediately observe an explicit linear $L_\star$ dependence in Equation (2). This arises from the fact that for the same fractional luminosity (or total dust cross-sectional area), the blow-out size of grains in the cascade is larger and hence the belt's dust mass M_{dust} in the smallest grains is higher around more luminous stars (e.g., Equation (16) in Matrà et al. 2017b). The grain collision rate R_{col} is dependent on the grains' cross-sectional area and hence on the belt's fractional luminosity, which we are keeping constant. Then, the mass-loss rate ($= M_{dust}R_{col}$) and therefore the CO mass in Equation (2) carries a luminosity dependence, because more luminous stars will have larger grains and hence, for a constant fractional luminosity, will host more massive belts.

Ultimately, the relation between the exocometary CO gas mass M_{CO} and $L_\star$ will also incorporate the luminosity dependence of other variables in Equation (2). To estimate the latter, we consider the sample of belts that have been resolved by ALMA (Matrà et al. 2018b) and searched for CO. Assuming $R = 73L_\star^{0.19}$ (Matrà et al. 2018a), a constant photodissociation timescale of 120 yr, a CO(+CO_2) mass fraction of 20%, a constant $\Delta R/R = 0.4$ (the average fractional width of the sample), $M_\star = L_\star^{0.25}$, and $f = (1.56 \times 10^{-3})L_\star^{0.2}$ (the best-fit from a simple regression of the observed f–$L_\star$ relation for the above sample), we find that we should expect $M_{CO} \propto L_\star^{1.37}$ (orange line in Figure 3, left panel).

At the same time, we plot the predicted exocometary CO gas mass when taking into account the true $[f, R, \Delta R]$ of each of the belts in the sample (gray bars in Figure 3, left), which will

more accurately reflect the scatter in the parameters going into Equations (2) and (3). In this case, the CO mass is calculated through Equation (2) for stars with $L_\star \geqslant 0.2\,L_\odot$. For TWA 7, we use the mass-loss rate from the collisional cascade $\dot{M}_{D_{min,sw}}$ derived in Section 4.3.1, while for AU Mic we rescale the mass-loss rate of TWA 7 according to the different stellar and belt parameters that enter Equation (3).

For each belt, we show the predicted range of exocometary CO gas masses for CO(+CO_2) ice mass fractions of 0.8%–80%; we also assume a photodissociation timescale of 120 yr (as expected if the interstellar UV radiation field were to dominate over the star's) for all belts except HR4796A, which is a belt with a small radius R around the most luminous star in our sample, therefore clearly subject to much faster photo-dissociation ($t_{phd} = 8$ yr, Kennedy et al. 2018). As expected, Figure 3 (left) shows that more luminous stars will, on average, host belts with a higher exocometary CO mass.

4.4.2. From Mass to Observed Line Fluxes: Comparing with Existing Data

Having established that exocometary gas release should produce an increased exocometary CO mass around more luminous stars, we then assess whether this can produce the observed trend of higher detection rates as a function of stellar luminosity. To do so, we use CO masses (Figure 3, left) to compute CO line fluxes (Figure 3, right) for the given line ($J = 2$–1 or $J = 3$–2) that was observed for each belt.

For simplicity we assume, for all belts, optically thin emission for an excitation temperature of 20 K (Matrà et al. 2015, Equation (2)), which is in between the excitation

temperatures (of 9–32 K) measured in belts where a CO line ratio was available (Kóspál et al. 2013; Hughes et al. 2017; Matrà et al. 2017a). Then, these predicted CO fluxes can be compared to the 5σ detection threshold actually achieved by ALMA observations of each target (horizontal bars; blue for $J = 2$–1, pink for $J = 3$–2). These were obtained from the literature (Kóspál et al. 2013; Lieman-Sifry et al. 2016; Marino et al. 2016, 2017, 2018; Booth et al. 2017, 2019; Matrà et al. 2017a, 2017b; Moór et al. 2017; Kennedy et al. 2018; Daley et al. 2019).[7]

Figure 3 (right) shows that, on average, the predicted CO flux increases as a function of stellar luminosity. This is as expected from the CO mass trend in the left panel, although with a shallower slope largely caused by the fact that, on average, higher luminosity stars lie further away from Earth. In contrast with the predicted CO fluxes increasing with stellar luminosity, the ALMA detection thresholds remain roughly constant throughout the luminosity range, reflecting the fact that all observations reached 5σ line flux sensitivities within less than an order of magnitude of $0.1\,\mathrm{Jy\,km\,s^{-1}}$.

The predicted CO flux increasing and the ALMA sensitivity remaining constant as a function of stellar luminosity shows that the exocometary gas release model would naturally produce an increasing occurrence rate for more luminous stars. In other words, the model produces, on average, more high luminosity than low luminosity system above the ALMA CO detection threshold. This explains the trend of increasing detection rates as a function of stellar luminosity found by Moór et al. (2017), and visually illustrated by the colors and line styles of Figure 3 (right; solid green for detected targets and dashed red for undetected targets).

We note that the specific aim of Figure 3 is to explain the stellar luminosity trend in the detection rates, and not to compare predicted fluxes to observed fluxes for each of the systems in our sample. The latter was done by Kral et al. (2017, 2018), who showed that the exocometary gas model can explain all current gas masses observed. Furthermore, the range of fluxes shown for each belt in Figure 3 only accounts for a range of $CO(+CO_2)$ mass fractions of 0.8%–80%, consistent with the values derived so far for exocomets and solar system comets (e.g., Figure 6 in Matrà et al. 2017b). This does not account for other uncertain model parameters which will also influence the flux prediction. For low CO mass belts, the parameter dominating the uncertainty is the unknown molecular excitation for observations of a single transition. For the most massive CO belts, there is also a potential for both extra shielding from CO and C I prolonging the photodissociation timescale, and for an optical depth greater than one for the observed millimeter transitions, where the latter has been found for some systems through isotopologue observations (e.g., Kóspál et al. 2013).

Nonetheless, exocometary gas release is currently the only viable model to explain the presence of CO in low mass systems, since the short photodissociation lifetime of CO requires continuous replenishment. We now show that the exocometary model can also explain the increasing detection

rates as a function of stellar luminosity, as well as the large CO masses observed in some systems (Kral et al. 2018). This gives further support to the idea that CO gas is ubiquitous in planetesimal belts around nearby stars, at least in the cold and bright (and hence mostly young) belts observed so far.

5. Conclusions

In this work, we presented the first ALMA detection of CO gas in a planetesimal belt around an M star, TWA 7. We reach the following conclusions.

1. TWA 7 hosts $(0.8$–$80) \times 10^{-6}\,M_\oplus$ of optically thin CO gas, which is consistent with being colocated with the millimeter dust disk and with being in Keplerian rotation around the star, with the east side moving away from Earth.

2. The intensity of CO-photodissociating FUV starlight around M dwarfs is dominated by emission from the stellar chromosphere/transition region. Therefore, close to the star where the contribution of the ISRF is negligible, the CO photodissociation rate is sensitively dependent on the overlap of chromospheric lines with the predissociative absorption bands of CO. Young M stars are very active, which means their CO photodissociation rates are, although smaller, not negligible compared to coeval A stars, particularly during flares.

3. For TWA 7, even assuming a low CO/H_2 ratio of 10^{-6}, H_2 shielding and CO self-shielding could only increase the CO photodissociation timescale from 100 to 1000 yr at 60 au. This means that any primordial CO would have been quickly removed, and the observed CO must be produced through exocometary gas release.

4. Exocometary gas release around an M dwarf through the collisional cascade differs from that around more massive stars. This is because the collisional cascade is affected by stellar wind-driven (as opposed to radiation pressure) removal of the smallest grains, setting the minimum size of the cascade.

5. We derive a $CO(+CO_2)$ mass fraction of TWA 7's exocomets of $\geqslant 70\%$. This is higher than other exocometary gas bearing belts and solar system comets, and may be explained by (1) uncertainties in the observationally determined minimum size of the cascade, (2) longer photodissociation timescales due to significant shielding of CO by atomic carbon produced as the CO photodissociates, or (3) an intrinsically higher $CO(+CO_2)$ content than other belts.

6. We analyze the stellar luminosity dependence of the occurrence rate of CO gas found by Moór et al. (2017). We show that this is naturally explained within the framework of our exocometary gas release model, combined with observational detection bias. There is thus no evidence that the presence of CO gas is linked to a specific subset of stars. This supports the idea that CO gas is ubiquitous among the currently surveyed sample of cold, large exocometary belts.

Overall, the population of detected belts and the dependence of their occurrence rate on host star luminosity are so far mostly consistent with a picture where exocometary gas is ubiquitous, with all stars releasing it at some level. However, deeper searches in a larger sample of belts, as well as detailed studies of the most CO-rich systems, are necessary to confirm that

---

[7] For reported detections, we took the uncertainty on the integrated line flux and subtracted the 10% ALMA flux calibration uncertainty in quadrature. For HD61005, the upper limit is not reported in Olofsson et al. (2016), so we calculated the uncertainty on the integrated line flux from the data set directly, as done for TWA 7 here. For the sources in Lieman-Sifry et al. (2016), the spatially and spectrally integrated uncertainty is measured assuming two different spatial apertures; we rescale all uncertainties to a common $2''$ aperture.

planetary systems do commonly release exocometary ices throughout their lifetimes.

Facility: ALMA.

Software: CASA (v5.1.0; McMullin et al. 2007), PHOENIX (e.g., Hauschildt 1993), SciPy (Jones et al. 2001), Matplotlib (Hunter 2007).
