Manipulating the valley degree of freedom as an information carrier has been a focused topic for both fundamental and applied research. Here, using first-principles calculations, we report the identification of monolayer CrX₂ (X= S, Se) as a novel two-dimensional valleytronic crystal. It shows large valley spin splitting in the valence band, attractive for the integration of valleytronics and spintronics. More importantly, through proximity coupling with monolayer CrCl₃, the valley polarization in monolayer CrX₂ is achieved, which can be further engineered by stacking patterns. Also, the valley polarization in monolayer CrX₂ can be obtained via magnetically doping V and Mn. Specially for V-doped monolayer CrSe₂, there are no impurity states in the band gap, beneficial for its practical applications. Our works thus provide not only exceptional two-dimensional valleytronic crystals but also promising ways for realizing valley polarizations in them.

**Introduction**

Two-dimensional (2D) valleytronic materials have recently attracted considerable attention¹,² with the development of 2D materials.³⁻⁸ In 2D valleytronic materials, the valley characterizes the local maximum in the valence band or the local minimum in the conduction band at the K and K' points. Therefore, carriers are endowed with an extra degree of freedom, namely the valley index, which is robust against lattice scattering as it has large separation in momentum space.⁹ Also, the valley index is associated with the valley-contrasting physical quantities.² Analogous to exploiting charge for electronics or spin for spintronics,¹⁰,¹¹ the valley index constitutes the binary states, forming the main
context of valleytronics. This results in a large amount of intriguing phenomena and potential applications, especially in information storage and processing.\textsuperscript{12-15} Although 2D valleytronic materials are highly desirable, up to now, only a few candidates are proposed, including graphene, VS\textsubscript{Se}, Tl\textsubscript{2}O, and 2D transition metal dichalcogenides (TMDs) MX\textsubscript{2} (M = V, Ta, Mo, W; X = S, Se, Te).\textsuperscript{16-22} Therefore, new 2D valleytronic materials remain to be discovered and are still urgently needed.

On the other hand, to make a valleytronic device, it is necessary to break the balance of carriers in the $K$ and $K'$ valleys, thereby achieving the valley polarization.\textsuperscript{9, 23} To that end, currently, several avenues are proposed. One is to use the circularly polarized optical pumping\textsuperscript{14, 15} since the orbital magnetic moments are opposite in the $K$ and $K'$ valleys. This approach has been well demonstrated in experiments to be able to realize valley polarization.\textsuperscript{13-15, 24-27} However, optical pumping is a dynamical process, which simply changes the chemical potential in the valleys and is not applicable for robust manipulation.\textsuperscript{18} Another avenue is to use magnetic field to induce spin polarization, which is accompanied by a valley polarization.\textsuperscript{28, 29} That is because the spin and valley indexes in 2D valleytronic materials are locked to each other. Although valley polarization is indeed achieved by applying external magnetic field experimentally, the effect is rather modest as 1T magnetic field can only lead to a splitting of 0.1-0.3 meV.\textsuperscript{30-32} Compared with these two approaches, recently utilizing atom doping\textsuperscript{20, 33-37} and magnetic semiconductor substrate\textsuperscript{38-44} are shown to be more effective ways to achieve valley polarization. Nevertheless, as the interaction between host material and the substrate/doping may deform the valley feature, the magnetic substrate or transition metal must be selected carefully.

In this work, we systematically investigate the electronic and valleytronic properties of monolayer \textit{CrX\textsubscript{2} (X= S, Se)} on the basis of first-principles calculations. Monolayer \textit{CrX\textsubscript{2} is a direct-gap semiconductor and harbors two inequivalent valleys at the $K$ and $K'$ points. Also, it exhibits a very large valley spin splitting in the valence band, providing a highly attractive candidate for research on valleytronics and spintronics. Moreover, we propose two effective strategies to produce valley polarization in monolayer \textit{CrX\textsubscript{2}, where the valley features are well preserved. One is through proximity coupling with monolayer \textit{CrCl\textsubscript{3}, which leads to valley polarization. And the induced valley polarization exhibits a stacking pattern-dependent behavior. Another is utilizing V and Mn doping. Particularly for the case of V-doped monolayer \textit{CrSe\textsubscript{2}, no impurity state appears in the band gap, which is favorable for practical applications. These compelling properties render monolayer \textit{CrX\textsubscript{2} an attractive platform for developing valleytronic devices.}

\textbf{Methods}
First-principles calculations are performed within density functional theory (DFT) as implemented in Vienna ab initio Simulation Package (VASP).\textsuperscript{45} To describe the electron-ion interaction, the projected augmented wave (PAW) approach is adopted.\textsuperscript{46} The generalized gradient approximation (GGA) in form of Perdew-Burke-Ernzerhof (PBE) functional is used to describe the exchange-correlation interaction.\textsuperscript{47} The cutoff energy is set to 500 eV. The vacuum space is set to be about 18 Å. The van der Waals interaction is treated by the DFT-D3 method.\textsuperscript{48} Structures are fully relaxed with the force tolerance of 0.01 eV/Å. The convergence criterion for electronic iteration is set to be $10^{-6}$ eV. A 7×7×1 and 9×9×1 k-point grid is used to sample the Brillouin zone for geometry optimization and static electronic calculations, respectively. The strong-correlated correction is considered with GGA + U method to deal with the Cr’s 3$d$ electrons.\textsuperscript{49} The effective onsite Coulomb interaction parameter (U) and exchange interaction parameter (J) are set to be 3.5 and 0.5 eV, respectively.\textsuperscript{20, 50-52} The spin-orbit coupling (SOC) effect is taken into account in electronic structure calculations. Berry curvatures are calculated using the WANNIER90 package.\textsuperscript{53} The phonon spectra is obtained using the PHONOPY code.\textsuperscript{54}

**Results and discussion**

It is known that CrX$_2$ can exist in 2H phase and 1T phase.\textsuperscript{55, 56} Previous works investigated the electronic and magnetic properties of 1T-CrX$_2$ and found that a strain can induce a state switch between ferromagnetic and antiferromagnetic.\textsuperscript{56} However, the inversion symmetry limits its valleytronic applications. Here, we focus on 2H-CrX$_2$ to investigate the valleytronic properties. Fig. 1a shows the crystal structures of monolayer CrX$_2$. It exhibits a hexagonal lattice, with a Cr atom layer sandwiched between two X atom layers. The lattice constants are found to be $a = b = 3.041$ Å for CrS$_2$ and $a = b = 3.173$ Å for CrSe$_2$, which agree well with previous works.\textsuperscript{55, 57, 58} To confirm the stability of CrX$_2$, we calculate its phonon spectra. As shown in Fig. S1, no imaginary frequency is observed in the whole Brillouin zone, indicating that CrX$_2$ is dynamically stable. The crystal symmetry of monolayer CrX$_2$ is D$_{6h}$, and hence its inversion symmetry is explicitly broken. The band structures of monolayer CrX$_2$ are shown in Fig. 1d and e. We can see that monolayer CrS$_2$ (CrSe$_2$) is a semiconductor with a direct band gap of 0.93 (0.75) eV. The valence band maximum (VBM) and conduction band minimum (CBM) both locate at the at the $K$ and $K'$ points, forming two energy-degenerate valleys. By comparing the band structures with and without considering SOC, we can see an interesting point. Namely, upon including SOC, both VBM and CBM experience a valley spin splitting, and thus the spin degeneracy of both VBM and CBM are lifted (see Fig. 2b). And as shown in Fig. 1d and e, the ordering of the spin-up and spin-down states at $K$ and $K'$ valleys are opposite,
which can be attributed to the time-reversal symmetry \( [E^{\uparrow}(k) = E^{\downarrow}(-k)] \). Accordingly, spin can be selectively excited through the optical selection rule.

It should be noted that the valley spin splitting in the valence band [68.5 (90.6) meV] of monolayer CrS\(_2\) (CrSe\(_2\)) is significantly large, although these values are smaller than that of transition metal dichalcogenides (0.1~0.5 eV).\(^9\),\(^35\),\(^59\) In contrast, the valley spin splitting in the conduction band is extremely small [4.1 (15.4) meV]. Such a difference is sought into the different orbital contributions of the VBM and CBM of monolayer CrX\(_2\). As shown in Fig. S2, the VBM of monolayer CrX\(_2\) is mainly from the \( d_{x^2-y^2}, xy \) orbitals of Cr and \( p_{x,y} \) orbitals of X. As Cs symmetry guarantees the out-of-plane potential gradient symmetry, the valley spin splitting in monolayer CrX\(_2\) mainly results from the in-plane potential gradient asymmetries. The in-plane character of these states combined with the strong SOC strength within the Cr atom results in the sizeable valley spin splitting in the valence band. While for the CBM, it is dominated by \( d_{z^2} \) orbital of Cr. The out-of-plane orientation of \( d_{z^2} \) orbital has slight impact on the valley spin splitting, resulting in the negligible value in the conduction band.

The blue and orange lines denote spin-up and spin-down states, respectively. The Fermi level is set to 0 eV.
Having estimated the $K$ and $K'$ valleys of monolayer CrX$_2$, we then explore how to generate and manipulate its valley polarization, which is indispensable for developing valleytronics devices. We first utilize magnetic proximity coupling in heterostructures composed of monolayer CrX$_2$ and a magnetic substrate to lift the valley degeneracy. Here, monolayer CrCl$_3$ is selected as the substrate due to two considerations. First, monolayer CrCl$_3$ has been well identified to be a magnetic semiconductor. And as shown in Fig. 1c, it has a large direct band gap of 1.51 eV. Second, the lattice mismatch between them is small. The CrX$_2$/CrCl$_3$ heterostructure is constructed using a 2 × 2 supercell of CrX$_2$ and a 1×1 unit cell of CrCl$_3$, which results in a lattice mismatch of 0.24% for CrS$_2$/CrCl$_3$ and 2.37% for CrSe$_2$/CrCl$_3$. To reveal influences of lattice mismatch on the magnetic coupling, we also investigate the band structures of I-CrX$_2$/CrCl$_3$ under strain of ±1%. As shown in Fig. S3, the lattice mismatch has little effect on the magnetic coupling between CrX$_2$ and CrCl$_3$. Such tiny mismatches are well desirable for experimental explorations. Moreover, bulk CrCl$_3$ has been successfully exfoliated down to the monolayer limit, offering the possibility for creating van der Waals heterostructures.

For CrX$_2$/CrCl$_3$ heterostructure, we consider three typical configurations, including I-CrX$_2$/CrCl$_3$ (two X atoms are above one Cr atom of CrCl$_3$), II-CrX$_2$/CrCl$_3$ (one Cr atom of CrX$_2$ is on top of the Cr atom of CrCl$_3$) and III-CrX$_2$/CrCl$_3$ (two X atoms and one Cr atom of CrX$_2$ are above two different Cr atoms of CrCl$_3$); see Fig. 2a. To estimate the relative stability among these configurations, we calculate their binding energies, which are defined as $E_b = E_{total} - E_{CrX_2} - E_{CrCl_3}$. Here $E_{total}$, $E_{CrX_2}$ and $E_{CrCl_3}$ represent the energy of CrX$_2$/CrCl$_3$ heterostructure, monolayer CrX$_2$ and monolayer CrCl$_3$, respectively. As listed in Tab. S1, these configurations all have negative binding energies, revealing their energetically stability. For more information about these configurations, please see Tab. S1. As listed in Tab. S2, the energy barrier for a physisorbed O$_2$ molecule to dissociate or chemisorb on the surface of CrX$_2$/CrCl$_3$ heterostructure is high, indicating the systems’ robust oxidation resistance at ambient conditions.

**Tab. 1.** The valley spin splittings of VB ($\Delta_{spin}^{v,K}/\Delta_{spin}^{v,K'}$) (in meV) and CB ($\Delta_{spin}^{c,K}/\Delta_{spin}^{c,K'}$) (in meV) at the $K/K'$ point for CrX$_2$/CrCl$_3$ heterostructures. The valley polarizations of VB (\(\Delta_{VB}\)) (in meV) and CB (\(\Delta_{CB}\)) (in meV) for CrX$_2$/CrCl$_3$ heterostructures.

The band structures of CrX$_2$/CrCl$_3$ heterostructure under different stacking configurations are shown in Fig. 2d, 2e and S4. We note that $K$ and $K'$ points of the primitive cell are folded to the $K'$ and $K$ points of the 2 × 2 supercell of CrX$_2$, respectively. Clearly, the three configurations share similar band features. In the absence of SOC, the spin-up and spin-down channels are asymmetric due to the broken time-reversal symmetry induced by the magnetic substrate CrCl$_3$. However, the $K$ and $K'$ valleys are still degenerate in energy. When including SOC, large valley spin splitting is observed at both $K$ and $K'$ valleys. And more importantly, as illustrated in Fig. 2c, the degeneracy between the $K$ and $K'$ valleys is lifted, producing the long-sought valley polarization. To quantify the valley polarization, we define $\Delta_{KK'} = E_K - E_{K'}$ as the energy difference between the VBM at the $K$ and $K'$ points. The corresponding results are summarized in Tab. 1, from which we can see that the values of valley polarizations in CrX$_2$/CrCl$_3$ are comparable to that of WSe$_2$/CrI$_3$. In Tab. 1, there is another interesting point we wish to address: as the valley spin splitting of VB is much larger than that of CB, the valley energy shift of CB and VB are similar. This discrepancy is sought into the combined effect of SOC and magnetic field. For the magnetic field, it induces similar spin splitting in VB and CB, and thus has little contribution to their difference. In this case, SOC plays a dominate role. And similar to free-standing monolayer CrX$_2$, SOC would induce a large (small) valley spin splitting in VB (CB) due to the orbital contribution. While for $\Delta_{VB}$ ($\Delta_{CB}$), it is the energy difference between the valleys at the $K$ and $K'$ points. Clearly, the SOC has similar contribution to the spin splitting at the two valleys in VB (CB) due to the similar orbital contribution, and thus the magnetic field plays a dominate role. That is why the absolute values of $\Delta_{VB}$ and $\Delta_{CB}$ are comparable. And although SOC has similar contribution to the absolute values of spin splitting at the two valleys in VB (CB), it induces opposite spin signs at two valleys. With these results in hand, we can understand why $\Delta_{VB}$ and $\Delta_{CB}$ have opposite signs.

Additionally, we find that the valley polarization is dependent on the stacking pattern. And I-CrX$_2$/CrCl$_3$ shows the largest valley polarizations among the three configurations. Therefore, the valley polarization in CrX$_2$/CrCl$_3$ can be engineered by modulating the stacking pattern, which holds
promise for practical applications. The stacking dependent valley polarization results from the variation of the layer and atom distances. As we mentioned above, the VBM and CBM of CrX$_2$/CrCl$_3$ are mainly from Cr atoms of CrX$_2$ (Cr1), while the local magnetic field is mainly provided by Cr atoms of CrCl$_3$ (Cr2). The coupling between Cr1 and Cr2 would influence the valley polarization. In detail, a short distance would cause a large valley polarization. And as expected, the distances of Cr1-Cr2 [$d_{Cr1-Cr2(I)} < d_{Cr1-Cr2(III)} < d_{Cr1-Cr2(II)}$] show consistent trend with the values of valley polarization (see Tab. 1 and S1).

**Fig. 2.** (a) Crystal structures of CrX$_2$/CrCl$_3$ heterostructure under different stacking configurations from top and side views. Schematic diagrams of the bands with SOC at the $K$ and $K'$ valleys for (b) monolayer CrX$_2$ and (c) CrX$_2$/CrCl$_3$ heterostructure. The blue and orange lines in (b) and (c) denote spin-up and spin-down states, respectively. Band structures of (d) I- CrS$_2$/CrCl$_3$ and (e) I- CrSe$_2$/CrCl$_3$ without (left) and with (right) SOC. The blue and orange lines denote spin-up and spin-down states, respectively. The Fermi level is set to 0 eV.

We then investigate the effect of magnetic doping on the valleytronic properties of monolayer CrX$_2$. Here, V and Mn atoms are selected as the doping atoms as their radius and electronegativity
are similar to that of Cr, thus inducing no significant structural deformation to the host material. To verify the stability of doped systems at ambient conditions, we calculate the energy barrier for a physisorbed O$_2$ molecule to dissociate or chemisorb on the surface of V/Mn-doped CrX$_2$. As listed in Tab. S3, the energy barrier is high, indicating that both systems are stable at ambient conditions. To simulate the doping effect, we use one V/Mn atom to replace one Cr atom from a 4 × 4 supercell of monolayer CrX$_2$. After doping with V/Mn, monolayer CrX$_2$ is spin-polarized. The total magnetic moment is found to be 1.0 $\mu_B$ for V/Mn-doped CrX$_2$. The rise of spin-polarization can be attributed to the fact that each V (Mn) atom has one less (more) valence electron than the Cr atom. And based on this fact, we can also understand why the introduced magnetic moments for both cases are 1.0 $\mu_B$.

To gain further insight into the magnetic properties, the spin density distributions of V/Mn-doped CrX$_2$ are depicted in Fig. 3. It can be seen that the induced magnetic moments are mainly localized around the dopants, and the contribution from the nearby host atoms are relatively small.

The band structures of V/Mn-doped CrX$_2$ are shown in Fig. 3. Since the time-reversal symmetry is broken, the energy degeneracy between two valleys of V/Mn-doped CrX$_2$ is expected to be lifted, i.e., $E_\uparrow(K) \neq E_\uparrow(K')$. As shown in Fig. 3, for all cases, the top valence band at the $K$ point is higher than that at the $K'$ point. Therefore, the valley polarization is also achieved in monolayer CrX$_2$ by magnetic doping of V/Mn. The valley polarizations for V/Mn-doped CrS$_2$ (CrSe$_2$) are as large as 40.4/65.8 (82.4/83.3) meV, significantly larger than that of tiny value generated by application of an external magnetic field (~0.10-0.24 meV/T).$^{29,32}$

As shown in Fig. 3f, there is a defect state locating closely to valence bands of V-doped CrS$_2$, which would deform the valleys in the valence bands. But fortunately, the valleys in the conduction bands lie far away from the defect state. While for Mn-doped CrS$_2$, although several defect states exist in the band gap, they lie far away from both the valance and conduction bands (see Fig. 3g). Considering the fact that the Fermi level crosses the bottom of the defect states, the valleys in the valence bands of Mn-doped CrS$_2$ are more favorable. A similar case is also observed in Mn-doped CrSe$_2$, in which the valleys in the conduction bands are deformed and the valleys in the valence bands are preserved; see Fig. 3i. Compared with these three systems, the case of V-doped CrSe$_2$ is more excellent. As shown in Fig. 3h, for V-doped CrSe$_2$, no impurity bands are introduced into band gap and the energy valleys are preserved well, which are ideal for practical application in valleytronic devices.
Fig. 3. (a) Crystal structure of V/Mn-doped monolayer CrX₂. Spin density distributions of (b) V- and (c) Mn-doped monolayer CrS₂. Spin density distributions of (d) V- and (e) Mn-doped monolayer CrSe₂. The yellow and green isosurfaces in (b-e) correspond to the spin-up and spin-down states, respectively. Band structures of (f) V- and (g) Mn-doped monolayer CrS₂. Band structures of (h) V- and (i) Mn-doped monolayer CrSe₂. The blue and orange lines denote spin-up and spin-down states, respectively. The Fermi level is set to 0 eV.

Because of the inversion symmetry breaking, the charge carriers in the K and K’ valleys of monolayer CrX₂ get a nonzero Berry curvature along the out-of-plane direction, which is the basis for realizing the valleytronics. We then take I-CrS₂/CrCl₃ and V-doped CrS₂ as examples to inspect the effect of magnetic proximity coupling and doping on the Berry curvature of monolayer CrX₂. The Berry curvatures are derived from the Kudo formula, which can be expressed as:

$$\Omega (k) = -\sum_n \sum_{n' \neq n} f_n \frac{2 \Im (\psi_{nk}|\nu_x|\psi_{n'k}) \langle \psi_{nk}|\nu_y|\psi_{n'k}\rangle}{(E_n - E_{n'})^2}.$$  

Here, $f_n$, $|\psi_{nk}\rangle$, and $\nu_{xy}$ are the Fermi-Dirac distribution function, the Bloch wave function with eigenvalue $E_n$, and the velocity operator along $x/y$ directions. The corresponding Berry curvatures as a contour map in the 2D Brillouin zone are displayed in Fig. 4a-c. For monolayer CrS₂, as shown in Fig. 4a, $\Omega (k)$ at the K and K’ valleys are sizeable and exhibit opposite signs. While for I-CrS₂/CrCl₃ and V-doped CrS₂, although the values of $\Omega (k)$ are slightly changed, they are still sizeable and feature opposite signs at the K and K’ valleys (Fig. 4b, 4c). This firmly confirms that the particular features of Berry curvature are preserved in I-CrS₂/CrCl₃ and V-doped CrS₂. The band structures of monolayer CrS₂, I-CrS₂/CrCl₃ and V-doped CrS₂ fitted by Wannier functions are shown in Fig. S5, which are in well agreement with DFT results.
Fig. 4. Contour maps of Berry curvatures of (a) monolayer CrS$_2$, (b) I-CrS$_2$/CrCl$_3$ and (c) V-doped CrS$_2$. (d) Illustration of valley Hall effect in monolayer CrX$_2$ with hole doping. (e) Illustration of anomalous valley Hall effect in valley polarized monolayer CrX$_2$ with hole doping. The red and blue ‘+’ in (d) and (e) represent the holes in K and K’ valleys, respectively. The blue and red arrows in (d) and (e) depict the spin directions of carriers.

Owning to the sign change of Berry curvatures in different valleys, the intriguing valley-contrasting physics is expected to be observed in monolayer CrX$_2$. Namely, in the presence of a longitudinal external electric field, carriers located in opposite valleys will achieve opposite transverse velocities related to driving force of $\Omega(k)$. For pristine monolayer CrX$_2$ with hole doping, the holes in the K and K’ valleys move to opposite directions of the sample under an in-plane electric field (see Fig. 4d.), giving rise to the spin/valley Hall effect. While for CrX$_2$/CrCl$_3$ and V/Mn-doped CrX$_2$, when hole doping them to shift the Fermi level between the K and K’ valleys, namely the spin polarization is 100%, as shown in Fig. 4e, spin-down holes from the K valley will move to the bottom of the sample under an in-plane electric field. The accumulated holes will result in a net charge/spin/valley current in the transverse direction. Therefore, the intriguing anomalous charge/spin/valley effect is achieved in monolayer CrX$_2$. We wish to emphasize that the accompanied anomalous charge/spin effect provide a measurable voltage for the anomalous valley effect. Moreover, when we reverse the magnetization direction of CrX$_2$/CrCl$_3$ and V/Mn-doped CrX$_2$ by an external magnetic field, spin-up holes from the K’ valley will move to the top of the sample under an in-plane electric field, leading a net charge/spin/valley current with opposite direction. It will also result in a measurable voltage but with opposite sign.
Conclusion

In conclusion, using first-principles calculation, we identify monolayer CrX$_2$ as a promising 2D valleytronic material. We find that monolayer CrX$_2$ is a direct-gap semiconductor. It exhibits two inequivalent valleys at the $K$ and $K'$ points and shows a very large valley spin splitting in the valence band. We further propose proximity coupling with monolayer CrCl$_3$ to realize the long-sought valley polarization in monolayer CrX$_2$. And the valley polarization in CrX$_2$/CrCl$_3$ can be engineered by the stacking pattern. Moreover, we reveal utilizing V and Mn doping can also lead to valley polarization in monolayer CrX$_2$. Specially for the case of V-doped monolayer CrSe$_2$, no defect state appears in the band gap, which is beneficial for practical applications. Our works not only highlight an exceptional 2D valleytronic crystals but also provide promising ways for realizing valley polarizations in them.
