ABSTRACT

We present the first ultraviolet (UV) and multi-epoch optical spectroscopy of 30 Dor 016, a massive O2-type star on the periphery of 30 Doradus in the Large Magellanic Cloud. The UV data were obtained with the Cosmic Origins Spectrograph on the *Hubble Space Telescope* as part of the Servicing Mission Observatory Verification program after Servicing Mission 4, and reveal #016 to have one of the fastest stellar winds known. From analysis of the C IV $\lambda\lambda 1548$ –51 doublet we find a terminal velocity, $v_\infty = 3450 \pm 50 \text{ km s}^{-1}$. Optical spectroscopy is from the VLT-FLAMES Tarantula Survey, from which we rule out a massive companion (with $2 \text{ days} < P < 1 \text{ yr}$) to a confidence of 98%. The radial velocity of #016 is offset from the systemic value by -85 km s^{-1} , suggesting that the star has traveled the 120 pc from the core of 30 Doradus as a runaway, ejected via dynamical interactions.

Key words: open clusters and associations: individual (30 Doradus) – stars: early-type – stars: fundamental parameters – stars: mass-loss

1. INTRODUCTION

30 Doradus in the Large Magellanic Cloud (LMC) is the richest H II region in the Local Group, providing an excellent template with which to study regions of intense star formation, and both stellar and cluster evolution. It harbors a significant fraction of the most massive and luminous stars known, with a rich population of the earliest O-type stars (e.g., Melnick 1985; Walborn & Blades 1997), particularly in R136, the dense cluster at its core (Massey & Hunter 1998).

The O3 spectral class was introduced by Walborn (1971) to accommodate stars in which He I $\lambda 4471$ was absent in moderate-resolution photographic spectra, compared to the very weak absorption seen in O4-type spectra. The classification scheme was extended further by Walborn et al. (2002) to include the new types of O2 and O3.5 to delineate the behavior of the N III, N IV, and N V features seen in the earliest types. Even in the age of large multi-object surveys only a few tens of stars are known with O2–O3.5 types. Although very rare, their influence is far-reaching as they are expected to evolve rapidly into nitrogen rich Wolf–Rayet stars (WN types), plausible progenitors of supernovae and, potentially, gamma-ray bursts (Smartt 2009).

Observations with the 2-degree Field (2dF) instrument at the Anglo-Australian Telescope revealed a new O2-type star on the western fringes of 30 Doradus (Figure 1), with a radial velocity of $\sim 85 \text{ km s}^{-1}$ lower than the systemic velocity of

nearby massive stars (e.g., Bosch et al. 2009). New multi-epoch spectroscopy of this star, 30 Dor 016 in the VLT-FLAMES Tarantula Survey (Evans et al. 2010), now enables us to rule out the presence of a close massive companion to a high level of confidence, suggesting that the star might have been ejected from the denser central region. Here, we combine these observations with new ultraviolet (UV) spectroscopy of #016, some of the first data taken with the Cosmic Origins Spectrograph (COS) on the *Hubble Space Telescope* (HST), which reveal the star to have one of the highest wind terminal velocities seen to date in any massive star.

2. OBSERVATIONS

2.1. UV Spectroscopy

30 Dor 016 ($\alpha = 05^{\text{h}}37^{\text{m}}08^{\text{s}}.88$, $\delta = -69^{\circ}07'20''.36$, J2000) was observed with HST-COS as part of the Servicing Mission Observatory Verification (SMOV) program in 2009 July using the G130M and G160M gratings in the far-UV channel. The data were obtained as part of a focus-check run early in the SMOV phase of COS operations so we do not have full wavelength coverage as the gratings were not moved. Out-of-focus exposures ($< 25\%$ of the total) were excluded when co-adding the spectra, with final exposure times of 5671 s (G130M) and 4511 s (G160M). Estimates of the signal-to-noise ratio (S/N) in the combined spectrum are complicated by the large number of metallic absorption lines in the spectra of hot stars, particularly while the instrument is still undergoing full characterization. Here, we use selected continuum regions that are relatively free of lines to estimate the noise, yielding $S/N \gtrsim 40$.

* Based on observations obtained at the European Southern Observatory Very Large Telescope in program 184.D-0222 and with the NASA/ESA *Hubble Space Telescope* in program 11484, obtained at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555.

Figure 1. Digital Sky Survey “IR” ($\sim I$ -band) image showing the location of 30 Dor 016 (encircled) relative to the 30 Dor complex.

Preliminary characterization of the COS on-orbit performance has found broad non-Gaussian wings in the line-spread function of the spectrograph owing to wavefront errors from the primary and secondary mirrors of the telescope (Ghavamian et al. 2009). This reduces the detection threshold for weak absorption features and modifies the profiles of saturated lines. To account for these effects, our models of the C IV line in Section 3 were convolved by the line-spread functions determined by the COS team.

The COS spectrum of #016 is shown in Figure 2, together with an *HST* Space Telescope Imaging Spectrograph (STIS) E140M spectrum from program 9434 (P.I. Lauroesch) of HDE 269810 (Sk -67° 211), classified as O2 III(f*) by Walborn et al. (2002). They are close twins, but with subtle differences—the most striking being the morphology of the C IV absorption and the P Cygni emission at He II $\lambda 1640$. Indeed, the C IV doublet in #016 is saturated to a large velocity, indicative of a very fast stellar wind.

2.2. Optical Data

Optical spectroscopy of #016 was obtained as part of two programs with 2dF, before and after the AAOmega upgrade (Sharp et al. 2006). Three 2dF-AAOmega spectra were obtained on 2006 February 22–23 (P.I. JVL), with a 2dF spectrum obtained on 2004 December 8 (P.I. IDH), as summarized in Table 1.

The star was also observed as part of the Tarantula Survey (full details to be published elsewhere). Observations of #016 with three of the standard FLAMES settings (LR02, LR03, and HR15N) were obtained over the period 2008 December 17–22. Pairs of exposures were taken in each observing block (OB), with three OBs observed at the LR02 and LR03 settings, and two at HR15N. Individual exposure times were 1815 s (LR02, LR03) and 2265 s (HR15N). The spectral coverage and resolution, as defined by the full width at half-maximum (FWHM) of the arc calibration lines, is given in Table 1.

The survey features repeat LR02 observations to detect radial velocity variables; for #016 these were obtained on 2009 January

29, February 28, and October 8 (epochs 4, 5, and 6 in Table 1, respectively). The modified Julian Dates (MJD) for each epoch are listed in Table 1. Each co-added pair has an S/N > 100.

2.2.1. Spectral Classification

Informed by the apparent absence of detectable radial-velocity variations (Section 2.2.2), the individual LR02 and LR03 spectra were co-added, then merged in the overlap region, yielding an S/N > 350.

The $\lambda\lambda 3950$ – 4750 Å region of #016 is shown in Figure 2, compared with spectra of HDE 269810 and HD 93129A from Walborn et al. (2002). The most notable feature in the spectrum of #016 is the strong N IV $\lambda 4058$ emission combined with an absence of N III $\lambda 4640$ emission, suggesting that the star is of the very earliest type in the existing classification framework. Also note the O IV $\lambda 4632$, Si IV $\lambda 4654$, and C IV $\lambda 4658$ emission, and the He II $\lambda 4686$ P Cygni profile. Accurate rectification of the $\lambda 4686$ and H α regions is a notorious problem in observations of O-type stars, but we see broadened wings to the He II line in both manual and scripted rectifications.

As in the UV, the spectrum of #016 is similar to that of HDE 269810. While the He II $\lambda 4686$ profile in #016 suggests a somewhat more luminous star compared to HDE 269810, it is not as remarkable as the emission seen in HD 93129A (O2 If*; Walborn et al. 2002), leading to our intermediate classification of O2 III-If*.

2.2.2. Stellar Radial Velocities

There are relatively few optical lines for radial velocity analysis in such an early-type spectrum. The Balmer hydrogen lines and He II $\lambda 4686$ are strongly affected by the wind, so do not provide a true diagnostic of the stellar radial velocity. Overplotting of the data from each epoch (including those from 2dF) revealed no significant velocity shifts nor broadening/asymmetries in the lines, suggesting that a high-mass companion is not present and that #016 is a prime candidate as an ejected, massive runaway from R136.

The xCORR routine in the DIPSO spectral analysis package (Howarth et al. 2004) was used to cross-correlate the co-added pairs of LR02 spectra with the first epoch of LR02 observations. The velocity offsets, Δv_r (see Table 1), are found from fits to the cross-correlation functions (CCFs) with Gaussian profiles generated using the DIPSO emission-line fitting (ELF) routine. Although the CCFs are not Gaussian, the ELF fits were restricted to the range $-100 \text{ km s}^{-1} < \Delta v_r < 100 \text{ km s}^{-1}$, yielding robust estimates with fitting errors of 3–4 km s^{-1} (i.e., one tenth of a resolution element). From ELF fits to the He II $\lambda\lambda 4026$, 4200, 4542 absorption, and Si IV $\lambda\lambda 4098$, 4116 emission lines, the mean heliocentric radial velocity for the first LR02 observations was $v_r = 191.8 \pm 1.4 \text{ km s}^{-1}$.

Using the same methods we also cross-correlated the relevant calibration arcs to investigate the wavelength stability of FLAMES. The instrument is remarkably stable over all of our observations, with a largest offset of $\Delta v_r = -0.3 \text{ km s}^{-1}$, found between the arcs for epochs 1 and 6 (i.e., separated by 10 months).

Table 1 also lists cross-correlation results for the regions of the LR03 and 2dF-AAOmega spectra which overlap with the LR02 data; good agreement is found within the velocity resolution of the respective data.

Figure 2. Upper panel: *HST*-COS spectrum of 30 Dor 016 and an *HST*-STIS spectrum of its near twin, HDE 269810 (both binned to 0.25 Å). The wind features identified are N v $\lambda\lambda$ 1239-43, O iv $\lambda\lambda$ 1339-44, O v λ 1371, C iv $\lambda\lambda$ 1548-51, He ii λ 1640, and N iv λ 1718. Lower panel: FLAMES spectrum of #016, illustrating its place in the luminosity sequence at type O2 compared to HD 93129A and HDE 269810. Emission lines identified in #016 are N iv λ 4058; Si iv $\lambda\lambda$ 4089, 4116, 4654; O iv λ 4632; C iv λ 4658. Absorption lines identified in HDE 269810 are He ii $\lambda\lambda$ 4026, 4200, 4542, 4686; N v $\lambda\lambda$ 4604, 4620. The CMFGEN model for #016 is overplotted in red.

(A color version of this figure is available in the online journal.)

2.2.3. Limits on a Binary Companion

To investigate the confidence to which we can rule out a close massive companion to #016, we used the method of Sana et al. (2009). In these calculations we adopted a $75 M_{\odot}$ primary, a bi-uniform period (P) distribution (with 50% of the simulated systems with $0.3 < \log P(\text{days}) < 1$ and with 50% with $1 < \log P(\text{days}) < 3.5$), uniform distributions of eccentricities and mass ratios (between 0 and 0.9, and 0.1 and 1.0, respectively), a random orientation in space, and a random periastron passage time.

Our observations allow us to rule out an O- or early B-type companion (with peak-to-peak variations $>20 \text{ km s}^{-1}$) with a period in the range 2 days $< P < 1 \text{ yr}$ at the 98.1% level. These results are only weakly dependent on the primary mass, with a variation of $\pm 1\%$ for a primary in the range of $50\text{--}90 M_{\odot}$.

3. TERMINAL WIND VELOCITY

The Sobolev with exact integration (SEI) method was used to calculate UV line profiles to estimate v_{∞} , the terminal wind velocity of #016. We used the ccp7 SEI code¹⁰ which is based on the method from Lamers et al. (1987). The observed C iv $\lambda\lambda$ 1548-51 doublet was blueshifted by 190 km s^{-1} (Section 2.2.2), then compared to the calculated profiles.

The code adopts a standard β -law to describe the acceleration of the stellar wind and includes a turbulence parameter, v_t (typically expressed as a fraction of v_{∞}), to account for stochastic deviations from the velocity prescription. Line profiles were calculated over a range of values of v_{∞} , β , and v_t , then convolved by the line-spread function noted in Section 2.1. The best

	1.25	...	53,789.430	-3.6
2dF [1200B]	2.75	...	53,347.564	...

Notes. Δv_r results from cross-correlation with the first epoch LR02 observations.

χ -squared fit (excluding the interstellar absorption features and the emission peak, where the SEI method is known to underestimate the flux by about 10%) is obtained with $v_\infty = 3450 \pm 50$ km s⁻¹, $\beta = 0.75 \pm 0.1$, $v_t = 0.02 \pm 0.01 v_\infty$. The optical depth law parameters in the code (α_1 and α_2) were set to 1. For saturated lines these can be varied to obtain subtly different fits to the redward part of the absorption component but with no significant impact on the derived velocities. When v_t is relatively small, the value of v_∞ obtained from fitting the line profile effectively corresponds to the blueward extent (i.e., v_{black}) of the saturated P Cygni profile.

This is one of the highest wind terminal velocities measured directly for an O-type star, behind only HDE 269810 ($v_\infty = 3750$ km s⁻¹; Walborn et al. 1995) and R136a-608¹¹ (O3 If*, $v_\infty = 3640$ km s⁻¹; Prinja & Crowther 1998).

4. QUANTITATIVE ANALYSIS

Physical properties for a subset of O2-type stars were presented by Walborn et al. (2004). We employed similar methods to inform our discussion of #016, using CMFGEN (Hillier & Miller 1998) which solves the radiative transfer equation in the co-moving frame, under the additional constraint of statistical equilibrium. The temperature structure follows from the assumption of radiative equilibrium. CMFGEN does not currently solve the momentum equation, so a density or velocity structure is required. The velocity for the supersonic part of the wind is parameterized with a classical β -type law ($\beta = 0.75$, from Section 3), which is connected to a hydrostatic density structure at depth, such that the velocity and its gradient match at the interface. The subsonic density structure is set using a line-blanketed, plane-parallel TLUSTY model (v.200; Lanz & Hubeny 2003) with $\log g = 3.75$ (preferred over $\log g = 4.0$). The atomic model is similar to that adopted by Walborn et al. (2004), including ions from H, He, C, N, O, Ne, Si, P, S, Ar, Fe, and Ni.

We assumed a depth-independent Doppler profile for all lines when solving for the atmospheric structure in the co-moving frame, and incoherent electron scattering and Stark broadening

for hydrogen and helium lines was included. A uniform turbulence of 50 km s⁻¹ was adopted in the calculation of the emergent spectrum in the observer's frame. Using the same methods as Walborn et al. (2010), a line-broadening parameter ($v \sin i$) of 88 ± 17 km s⁻¹ was found from the optical spectra. Clumping was incorporated using a volume filling factor, f , as described by Hillier et al. (2003), with a typical value of $f = 0.1$ resulting in a reduction in mass-loss rate by a factor of $\sqrt{(1/f)} \sim 3$.

4.1. Spectroscopic Results

Based upon the observed UV to near-IR spectral energy distribution and the H α and He II $\lambda\lambda 1640, 4686$ wind features (with $v_\infty = 3450$ km s⁻¹), we estimated the stellar temperature, luminosity and mass-loss rate of #016 simultaneously.

For an adopted LMC distance of 49 kpc (distance modulus = 18.45), the UV spectrophotometry and optical¹² and near-IR photometry¹³ of #016 can be reproduced with interstellar extinctions of $E(B - V) = 0.07$ (foreground) and 0.27 (LMC), using standard Galactic and LMC (field) extinction laws (Seaton 1979; Howarth 1983) and a stellar luminosity of $L_* = 1.2 \times 10^6 L_\odot$, as shown in Figure 3. The relatively large local extinction is supported by the strong $\lambda 4428$ diffuse interstellar band, which is at a comparable radial velocity to #016.

In the absence of measurable He I $\lambda 4471$ absorption, a combination of optical nitrogen lines (N IV $\lambda 4058$, N V $\lambda\lambda 4603\text{--}20$) and UV oxygen lines (O IV $\lambda\lambda 1339\text{--}44$, O V $\lambda 1371$) was used to derive an estimated effective temperature (T_{eff}) of 50 kK for #016. This is a compromise between the available diagnostics—the optical N V lines favor a temperature some 5%–10% higher, while the UV O IV suggests 10% lower—but the strong N IV $\lambda 1718$ P Cygni profile and negligible S V $\lambda 1501$ line both firmly support $T_{\text{eff}} = 50$ kK. Given the adopted wind parameters, a slightly greater broadening profile was preferred ($v \sin i \sim 150$ km s⁻¹) in the final model than determined above.

A range of nitrogen abundances were considered, adopting $X_N = 0.08\%$ by mass, which is substantially greater than the interstellar abundance in the LMC (0.016%; Russell & Dopita 1990). For carbon and oxygen we adopt $X_C = 0.08\%$ and $X_O = 0.2\%$ by mass, slightly below the results from Dufour (1984) and Russell & Dopita (1990) for the interstellar medium (0.095% and 0.35%, respectively), although the UV oxygen diagnostics are relatively insensitive to abundance changes.

The adopted model is shown in Figures 2 and 3, including allowance for an LMC neutral hydrogen column density of $10^{21.6}$ cm⁻². In general, the fits are satisfactory, with a few exceptions. The UV P Cygni absorption troughs of O V $\lambda 1371$ and N IV $\lambda 1718$ extend too far blueward, although the majority of the “iron forest” (Fe V–VI) features are well matched. As with the temperature, the adopted mass-loss rate ($\dot{M} = 3 \times 10^{-6} M_\odot \text{ yr}^{-1}$) is a compromise between the available diagnostics (He II $\lambda\lambda 1640, 4686$ and H α). Weak metallic lines in the optical are, in general, reproduced satisfactorily, e.g., Si IV $\lambda\lambda 4089\text{--}4116$, O IV $\lambda 4632$, and the blend of C IV $\lambda 4658$ and O IV $\lambda 4654, 4663$. A more detailed treatment of #016 (including the role of clumping, line-broadening, and the wind acceleration and turbulence) is beyond the scope of this Letter and will be presented elsewhere.

A summary of physical and wind parameters of #016 is provided in Table 2, compared with those for HDE 269810

¹² $U = 12.62$, $B = 13.53$, $V = 13.49$, $R = 13.43$ (Massey 2002).

¹³ $J = 13.38$, $H = 13.35$, $K_s = 13.36$ (Two Micron All Sky Survey; Skrutskie et al. 2006).

¹¹ Star 36 from Massey & Hunter (1998).

X_C (%)	0.08	0.06
X_N (%)	0.08	0.03
X_O (%)	0.2	0.3

Notes. Mass estimates are obtained from non-rotating evolutionary models at LMC metallicity (R. Hirschi 2010, private communication). Metal abundances are reliable to within 50% (N), or a factor of 2 (C and O).

from Walborn et al. (2004). We have also compared our results with LMC-metallicity, non-rotating evolutionary predictions (R. Hirschi 2010, private communication) calculated with the mass-loss recipe of Vink et al. (2001). This approach is supported by our derived mass-loss rate, which agrees with theoretical predictions to within ~ 0.05 dex for #016. We obtain the best agreement for a stellar mass of $\sim 90 M_{\odot}$ at an age of ~ 1 Myr, corresponding to $\log g \sim 4.0$. In contrast, the spectroscopic gravity suggests a considerably lower mass of $\sim 50 M_{\odot}$. Using the evolutionary mass to calculate the escape velocity, v_{esc} , our measured terminal velocity is in excellent agreement with the expected value using the empirical relation $v_{\infty} \sim 2.6 v_{\text{esc}}$ (Lamers et al. 1995), as well as new predictions for the velocity structure of massive star winds (L. Muijres et al. 2010, in preparation).

5. 30 DOR 016 AS A MASSIVE RUNAWAY

30 Dor 016 is located at the end of an extended rarefied filament of nebular gas, at a radial distance of ~ 8.25 (120 pc in projection) west–southwest of R136, and 4.75 (70 pc) from the

less dense cluster NGC 2060. The [O III] emission superimposed on the stellar spectrum has a peak velocity of ~ 275 km s $^{-1}$, with some asymmetry toward slightly lower velocities but with no evidence for a second component matching the velocity of #016. This suggests #016 did not form locally and is a *bona fide* runaway star.

Further analysis of the stellar and gas dynamics in this region is warranted to complete our picture of the origins of #016, e.g., van Loon & Zijlstra (2001) found molecular gas to the southeast of R136 at a comparable radial velocity to the star. At present, we lack proper motions at useful precision to constrain its transverse velocity: $\mu_{\alpha} = 1.2 \pm 5.9$, $\mu_{\delta} = 1.5 \pm 5.9$ mas yr $^{-1}$ from UCAC2; $\mu_{\alpha} = 2.8 \pm 3.8$, $\mu_{\delta} = -4.3 \pm 3.8$ mas yr $^{-1}$ from UCAC3 (and flagged as uncertain; Zacharias et al. 2010). *HST* imaging of this region would provide much improved constraints (e.g., the precision achieved by Kallivayalil et al. 2006), and in the longer term, the *Gaia* mission should deliver transverse velocities in the LMC to a few km s $^{-1}$.

There are two other O2-type stars (Sk−68° 137 and BI 253) to the north and northwest of 30 Dor, which were proposed as runaways by Walborn et al. (2002). BI 253 has also been observed within the Tarantula Survey, but from preliminary inspection of its spectra, its radial velocity appears consistent with this part of the LMC. The case of #016 is also reminiscent of the discovery of N11-026 (O2.5 III(f*)), suggested as a runaway by Evans et al. (2006).

Runaway stars are thought to result from either dynamical interaction in massive dense clusters, or via a kick from a supernova explosion in a binary system, with the more massive star exploding first (see, e.g., Gvaramadze et al. 2009, and references therein). It is generally accepted that R136 is sufficiently young (1–2 Myr) that its most massive stars have yet to explode as supernovae. This implies that, if from R136, #016 must have been ejected through dynamical interaction, one of the clearest cases to date in support of this mechanism. This is vitally important as dynamical interactions in massive clusters are thought to be a possible mechanism for producing stellar mergers and very massive stars (with masses $> 140 M_{\odot}$) which might subsequently end their lives as pair-instability supernovae,

of broader relevance to the early ages of the universe when such massive stars are thought to be common (e.g., Heger et al. 2003; Gal-Yam et al. 2009).

We thank Alex de Koter, Paco Najarro, and the referee, Hans Zinnecker, for their helpful comments.
