Abstract

Dust-obscured galaxies (DOGs), which are observationally characterized as faint in the optical and bright in the infrared, are the final stage of galaxy mergers and are essential objects in the evolution of galaxies and active galactic nuclei (AGNs). However, the relationship between the torus-scale gas dynamics around AGNs and the DOGs' lifetime remains unclear. We obtained the evolution of the spectral energy distributions (SEDs) of a galaxy merger system with AGN feedback from postprocessed pseudo-observations based on an N-body/smoothed particle hydrodynamics (SPH) simulation. We focused on a late-stage merger of two identical galaxies with a supermassive black hole (SMBH) of 10^8 $M_\odot$. We found that the infrared luminosity of the system reaches ultra- and hyperluminous infrared galaxy classes (10^{12} and 10^{13} $L_\odot$, respectively). The DOG phase corresponds to a state in which the AGNs are buried in dense gas and dust, with the infrared luminosity exceeding 3.3×10^{12} $L_\odot$. We also identified subcategories of DOGs, namely bump and power-law DOGs, from the SEDs and their evolution. The bump DOGs tend to evolve to power-law DOGs over several Myrs. We found that contribution from the hot dust around the nucleus in the infrared radiation is essential for identifying the system as a power-law DOG; the gas and dust are distributed nonspherically around the nucleus, therefore, the observed properties of DOGs depend on the viewing angle. In our model, the lifetime of merger-driven DOGs is less than 4 Myr, suggesting that the observed DOG phase is a brief aspect of galaxy mergers.

1. Introduction

Galactic collisions have received much attention as a possible explanation for the formation of supermassive black holes (SMBHs) and their parent galaxy relationships. For example, Hopkins et al. (2008) presented a scenario of ultraluminous and luminous infrared galaxy (U/LIRG)[7] formation by major mergers. In gas-rich mergers, large amounts of gas and dust fall into the center of the galaxies because of galaxy–galaxy interactions, triggering nuclear starbursts and active galactic nuclei (AGNs). AGNs will expectedly be buried in a dense interstellar medium (ISM) for at least a certain period during this process (Hickox & Alexander 2018). In fact, Ricci et al. (2017) claimed that galaxies in the late phase of mergers have a higher fraction of Compton-thick AGNs with hydrogen column density $N_H \geqslant 2 \times 10^{24}\,\mathrm{cm}^{-2}$ than those that are isolated or in the early merging phase (see also Yamada et al. 2021). The mass accretion rate onto the nuclei can be enhanced during the buried phase (Kawaguchi et al. 2020), which is also essential for understanding the formation of SMBHs during galaxy formation.

Dust-obscured galaxies (DOGs) could be representative galaxies in the late stages of galaxy mergers, and they could evolve into quasars or red elliptical galaxies (Dey et al. 2008). This scenario is consistent with the fact that the population density of DOGs and quasars, as well as the cosmic star formation rate (SFR), commonly peaks around the redshift $z \sim 2$ (Hopkins 2004; Hopkins et al. 2007). DOGs are characterized as being faint in the optical and bright in the infrared; throughout this paper, we use the criteria of the color between the R band and the Spitzer 24 μm band $R - [24] > 14.0$ in Vega magnitude, which is equivalent to $F_{24\mu m}/F_R \geqslant 982$, and the Spitzer 24 μm band flux $F_{24\mu m} \geqslant 0.3$ mJy (Dey et al. 2008).

DOGs can be divided into two subcategories, namely, "bump DOGs" and "power-law DOGs" (hereafter PL DOGs) (Dey et al. 2008). The spectrum of bump DOGs is characterized by a bump in the spectral energy distribution (SED) at 1.6 μm and polycyclic aromatic hydrocarbon (PAH) emissions. Alternately, PL DOGs are characterized by a power-law spectrum in the optical and infrared wavelengths. Although their origin is still unclear, it is often considered that active star formation contributes to the SEDs of bump DOGs (Dey et al. 2008; Melbourne et al. 2012). It has also been reported that the population ratio of PL DOGs to bump DOGs correlates to $F_{24\mu m}$ (Dey et al. 2008; Melbourne et al. 2012; Toba et al. 2015). In addition, PL DOGs tend to have weaker PAH emissions and a higher $F_{24\mu m}$ than bump DOGs. These weak PAH emissions are usually regarded as a sign of AGN activity (Houck et al. 2005; Yan et al. 2007) and thus explain why PL

---

[7] LIRGs are galaxies with total infrared emissions brighter than 10^{11} $L_\odot$ and less than 10^{12} $L_\odot$ and ULIRGs are those with total infrared emissions of 10^{12} $L_\odot$ or higher.

DOGs are often considered to be AGN-dominated objects. However, this interpretation was not statistically confirmed by X-ray surveys of DOGs. The structure in the central kpc region has not been elucidated due to DOGs being mainly found at high redshift ($z > 1$). Stated differently, no observed evidence confirms how the AGNs, if present in the core of DOGs, are obscured by gas and dust, the distributions of which are generally not spherically symmetric. Ideally, the color and infrared (IR) flux should be affected by the geometry and distribution of the gas in the central 100 pc. The difference between PL DOGs and bump DOGs in terms of their structures is also an open question. Moreover, there is no theoretical understanding of the relationship between AGN activity and PL DOGs.

Numerical modeling of the galaxy–galaxy merger helps in studying the origin of DOGs. For example, Narayanan et al. (2010) performed galaxy–galaxy merger simulations at redshift 2. They found that the mid-IR SED of the system evolves from bump type to power-law type during the final coalescence stage. However, the spatial resolution from previous simulations of gas-rich mergers is not necessarily fine enough to resolve the dusty torus in which SMBHs are deeply buried. Narayanan et al. (2010) used a 100 pc resolution; therefore, it was necessary to introduce a subgrid model to represent the gas dynamics and structures around the SMBH (see also Crain et al. 2015). Blecha et al. (2018) studied the evolution of gas-rich merger systems using the N-body/smoothed particle hydrodynamics (SPH) code GADGET-3 with a spatial resolution of 23–48 pc and a mass resolution of $2.8 \times 10^5 \, M_\odot$. More recently, Yang et al. (2021) performed similar simulations for less massive galaxies with smaller BHs (1.5–$3 \times 10^6 \, M_\odot$) using GADGET-2 with spatial resolutions and masses of 20 pc and $4.6 \times 10^3 \, M_\odot$, respectively. The geometry and internal distribution of the gas and dust in $r < 100$ pc are crucial for the multiwavelength observational properties of AGNs (Schartmann et al. 2014; Wada et al. 2016; Izumi et al. 2018). For example, molecular gas around AGNs has recently been resolved by ALMA (García-Burillo et al. 2016; Izumi et al. 2018; Combes et al. 2019), which showed that the size of the molecular tori is typically less than 30 pc and that they are characterized by complicated kinematic structures (Imanishi et al. 2018, 2021). Moreover, the mass accretion rate to the SMBH can be affected by AGN feedback at $r \sim$ several tens of pc (Kawaguchi et al. 2020). Therefore, gas dynamics resolution in the torus scale (i.e., several tens of parsecs) is required to understand the origin of DOGs.

In this study, we focused on the final phase of galaxy mergers to reveal how the shielding of SMBHs evolves with time. We modeled the interaction of approximately 1 kpc cores in two galactic centers (see Section 2.1.2), assuming that the mass accretion toward the galactic nuclei is dominated by dense gas in the galactic central region. This ensures better spatial (4 pc) and SPH mass (1000 $M_\odot$) resolutions than previous gas-rich major merger simulations (for example, Narayanan et al. 2010; Blecha et al. 2018; Yang et al. 2021).[8] The formation and evolution of the merger system were studied by postprocessed pseudo-observations using the radiation

transfer simulation code RADMC-3D (Dullemond et al. 2012). Note that we do not fully resolve the gas dynamics on the accretion disk scale in the late stages of galaxy mergers. However, with the spatial resolution in our simulations, we can resolve three-dimensional structures of the gas on the dust-torus scale, which is essential for the obscuring properties of the AGNs. Then we can discuss, for example, how the properties of DOGs depend on the line-of-sight directions. We can also investigate the evolution of SEDs during the mergers with a finer time resolution than in previous simulations.

The remainder of this paper is organized as follows. Section 2 describes the simulation methods and the models. In Section 3.1, we investigate the time evolution of gas density and mass accretion rates. In Sections 3.2 and 3.3, we present pseudo-observation results. The evolution of the infrared luminosity and color calculated based on the SED and the column density during the DOG phase and the relationship between the bump and PL DOGs are discussed in Section 4.

Unless otherwise noted, all magnitudes in this study refer to the Vega system. In addition, a flat universe of $H_0 = 70 \, \mathrm{km \, s^{-1} \, Mpc^{-1}}$, $\Omega_M = 0.3$, and $\Omega_\lambda = 0.7$ was assumed.

2. Models and Methods

We simulated the interaction of galactic nuclei with supermassive black holes (SMBHs) in the final phase of a galaxy merger using the N-body/SPH simulation code ASURA (Saitoh et al. 2008, 2009; Saitoh & Makino 2013). The results obtained from ASURA were used as inputs for RADMC-3D (Dullemond et al. 2012) to calculate the evolution of SEDs.

2.1. Merger Simulations

2.1.1. N-body/SPH Simulations by ASURA

The dynamics of the interstellar medium in a merger system are calculated using smoothed pseudo-density SPH (SPSPH; Yamamoto et al. 2015). Gravitational forces were computed using a parallel tree algorithm. The tolerance parameter was set to 0.5.

Star formation and supernova explosions were implemented based on Saitoh et al. (2008). The four conditions under which SPH particles are converted into star particles are (1) hydrogen number density $n_H > 400 \, \mathrm{cm^{-3}}$, (2) gas temperature $T_{gas} < 100$ K, (3) $\nabla \cdot v_{SPH} < 0$, where v_{SPH} is the velocity of the SPH particle, and (4) $\Delta Q < 0$, where ΔQ is the thermal energy received by an SPH particle in a time step. SPH particles satisfying these conditions are converted to star particles according to the local Schmidt's law (Schmidt 1959). The star formation rate (SFR) is determined as $C_* \rho_{gas}/t_{ff}$, where C_* is a dimensionless star formation efficiency parameter set to 0.033, herein following Saitoh et al. (2008), ρ_{gas} is the local gas density, and t_{ff} is the freefall time. The initial mass function of the stellar particle was chosen as in Salpeter (1955). The supernova explosion was introduced based on Okamoto et al. (2008), and the stellar particles underwent a probabilistic Type II supernova explosion. We assume that a single supernova explosion provides 10^{51} erg as thermal energy to the surrounding SPH particles weighted by the spline function. Optically thin radiative cooling was assumed for the gas at 10 K–10^8 K (Wada et al. 2009) with solar metallicity. Far-ultraviolet radiation and photoelectric heating were also considered.

---

[8] In the most recent cosmological simulations of quasar fueling, Anglés-Alcázar et al. (2021) attained a sub-pc spatial resolution in a $10^{12} \, M_\odot$ halo using a Lagrangian refinement technique. Their model is intended to model the fueling of a single SMBH without AGN feedback and does not treat galactic collisions.

Table 1
Parameters of the Premerger System

SMBH		Stellar System				Gas Disk				ϵ^{k}	$\eta_{\text{AGN}}{}^{\text{l}}$

Figure 1. Initial setup of the merger system. The two identical systems were merged. Each has a supermassive black hole (SMBH) of $10^8 M_\odot$, a rotationally supported gas disk with a mass of $4 \times 10^9 M_\odot$ and angular momentum in the z-axis direction, and a spherical stellar system of $2 \times 10^{10} M_\odot$.

2.1.2. Merger Models

Here, we focus on the final phase of a galaxy–galaxy merger to study how the two BHs interact with the gas in the central kpc region. We did not consider galactic disks or dark matter halos. The model is based on Kawaguchi et al. (2020), who studied the interactions between SMBHs and the ISM in the central subkiloparsec region using the N-body/SPH code ASURA. As an initial condition, we prepared two identical systems, schematically represented in Figure 1. Each system consists of three components: an SMBH ($M_{\text{BH}} = 10^8 M_\odot$), a spherical stellar system ($M_{\text{star}} = 2 \times 10^{10} M_\odot$), and an axisymmetric rotating gas disk ($M_{\text{gas}} = 4 \times 10^9 M_\odot$) (see Figure 1 and Table 1).

The initial stellar system has a Plummer mass distribution, and the initial gas disk has a uniform density and a radius of 800 pc in rotational equilibrium (for example, Sorai et al. 2002; Herrero-Illana et al. 2012). We posit that mass accretion toward the galactic nucleus is dominated by dense gas and stars in the galactic central kpc region. The stellar system and gas disk are represented by 2×10^6 N-body and 4×10^6 SPH particles, respectively. We represent a stellar sphere assuming a Plummer model (i.e., the gravitational potential $\Phi(r) = -GM_{\text{star}} / \sqrt{r^2 + R_c^2}$) with $M_{\text{star}} = 2 \times 10^{10} M_\odot$ and core radius $R_c = 800$ pc.

The initial positions and velocities for each system are listed in Table 2. The gas disks of the two identical systems were coplanar, and their spins were prograde. Here, we define a Cartesian coordinate such that the origin is the center of one system (System 1), the x-axis is the direction to the other system (System 2), and the z-axis is parallel to the disk spins. System 2

Table 2
Relative Velocity and Position

	Position (kpc)	Velocity (pc Myr^{-1})
System 1	(0,0,0)	(0,0,0)
System 2	(3.5,0,0)	(0,100,0)

is initially at $(x, y, z) = (3.5, 0, 0)$ kpc and has $(v_x, v_y, v_z) = (0, 100, 0)$ pc Myr^{-1} (Table 2). Therefore, the entire merging system's orbit is coplanar with the gas disks (x–y plane), and its rotational axis is parallel and prograde with the gas disk spins (z-axis). Kawaguchi et al. (2020) found that there is no significant difference between prograde and retrograde collisions in terms of the mass accretion toward SMBHs after studying collisions between galactic cores with various orbits and spin vectors using a similar numerical method as in this paper. Therefore, we focused on prograde collisions.

2.1.3. Mass Accretion and AGN Feedback

An SPH particle is assumed to have accreted to a BH when the SPH particle enters the accretion radius (r_{acc}) from the BH particle and the following two conditions are satisfied: (1) The kinetic energy of the SPH particle is smaller than the gravitational energy, and (2) the angular momentum of the SPH particle is smaller than $J_{\text{acc}} = r_{\text{acc}} \sqrt{GM_{\text{BH}}/(r_{\text{acc}}^2 + \epsilon^2)^{1/2}}$, where ϵ is the gravitational softening. In this study, we assumed $\epsilon = 4.0$ pc and $r_{\text{acc}} = 6.4$ pc. The accretion radius should be larger than the softening radius to resolve the accretion process well. However, if r_{acc} is larger than the typical torus scale ($\sim$10–20 pc), the accretion rate toward the sink particle would be overestimated. We then assume $r_{\text{acc}} = 6.4$ pc to resolve the gas dynamics near the gravitational softening radius.

The isotropic AGN feedback provides the thermal energy ($\Delta E = \eta_{\text{AGN}} \dot{M}_{\text{gas}} c^2$) weighted by the spline function to 96–272 SPH particles in the vicinity of each BH particle. The AGN feedback radius is defined as the number of SPH particles within the radius that satisfies a range (96–272; the average is 145).[9] $\dot{M}_{\text{gas}}$ is the gas mass accretion rate of a BH particle per step at r_{acc}. The η_{AGN} is a free parameter representing the energy-loading efficiency, that is, a fraction of the heat energy received by the SPH particles in an arbitrary radius around the BH particles. Note that the AGN feedback implemented here does not exactly model the radiative and mechanical feedback from the AGNs to the circumnuclear gas in real galaxies. In other words, the parameter is not determined from first principles. This parameter phenomenologically expresses the

---

[9] To seek the exact number of SPH particles every time step is computationally costly, especially for dense regions near sink particles.
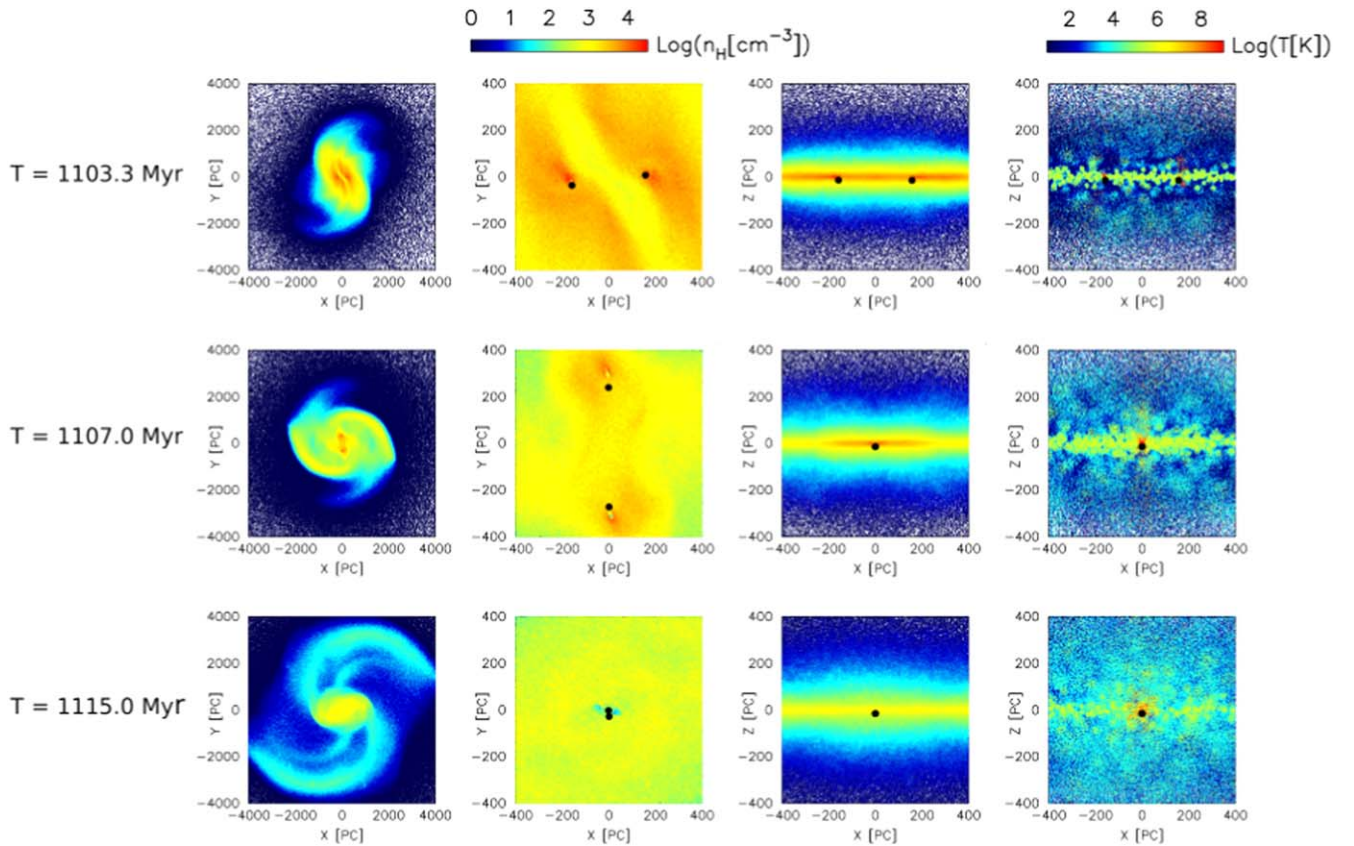

Figure 2. Gas density distribution ($n_{\rm H}[{\rm cm}^{-3}]$) in the first to third columns from the left and gas temperature (T[K]) in the rightmost column. From top to bottom, $t = 1103.3$, 1107.0, and 1115.0 Myr. Note that, here, the coordinates are shifted parallel to those in Figure 1 such that the origin is the center of gravity of the two BHs. Black circles denote the positions of the two BHs.

feedback process in a finite spatial resolution (i.e., 4 pc in this study). The relevant feedback fraction depends on the numerical methods, spatial resolution, and equation of state of the ISM; therefore, it is determined heuristically (see, for example, Hopkins et al. 2016). Kawaguchi et al. (2020) suggested in their *N*-body/SPH simulations of mergers that when $\eta_{\rm AGN} = 2.0\%$, the gas around the BH particles is blown away by the energy injection associated with the mass accretion; as a result, the mass accretion to the BH particles cannot be maintained. They found that mass accretion and AGN feedback could coexist for $\eta_{\rm AGN} = 0.2\%$. We also used this number in this study. The physical scale in which thermal energy is supplied is usually several tens of parsecs, depending on the gas density around the BH particles. However, in high-density regions, radiative cooling exceeds AGN feedback heating. In our simulation, the cooling of SPH particles that receive AGN feedback energy was set to be inactive for 10 time steps to ensure the hot gas produced by the AGN feedback interacts with its surroundings. This short period (10 steps = 10–10^3 yr) for which the cooling is stopped can be justified because it is shorter than the sound-crossing time of each SPH particle.[10]

2.2. Radiative Transfer Simulations

Snapshots obtained from the merger simulations described in Section 2.1 were used to calculate the SED evolution using

RADMC-3D, which is a Monte Carlo radiation transport code (Dullemond et al. 2012).

In this study, we considered two types of radiation sources: AGNs associated with the two SMBHs and star clusters consisting of newly formed young stars and bulge stars. The spectrum of each AGN depends on the bolometric luminosity $L_{\rm bol} = \varepsilon \dot{M}_{\rm gas} c^2$, where the energy conversion efficiency $\varepsilon = 0.1$, and $\dot{M}_{\rm gas}$ is the gas mass accretion rate of the SMBH averaged over 0.1 Myr.

The spectrum of each AGN was obtained from the templates contained in the Cloudy code (Ferland et al. 1998). In the code, we set four parameters to define a typical AGN SED consisting of multiple continuum components as follows. First, the temperature of the big blue bump was set to 1.5×10^5 K. Second, the X-ray to UV ratio α_{ox} was assumed to be -1.4, which is a typical value in AGNs (Zamorani et al. 1981; Lusso et al. 2010). In addition, we assumed that α_{uv}, which determines the low-energy slope of the big blue bump, and α_x, which determines the slope of the power-law X-ray component, were -0.5 (Francis 1993; Natali et al. 1998) and -1.0 (Mateos et al. 2010; Waddell & Gallo 2020), respectively. For stellar clusters, we assumed single stellar population (SSP) models; their spectra were obtained using Pégase.3 (Fioc & Rocca-Volmerange 2019). The initial mass function of an SSP set Salpeter (1955) and the spectrum of the SSP depend on the formation time.

We assumed that the spatial distributions of gas and dust were the same as the gas-to-dust mass ratio of 50 (Toba et al. 2017a). The size distribution of the dust grains was obtained
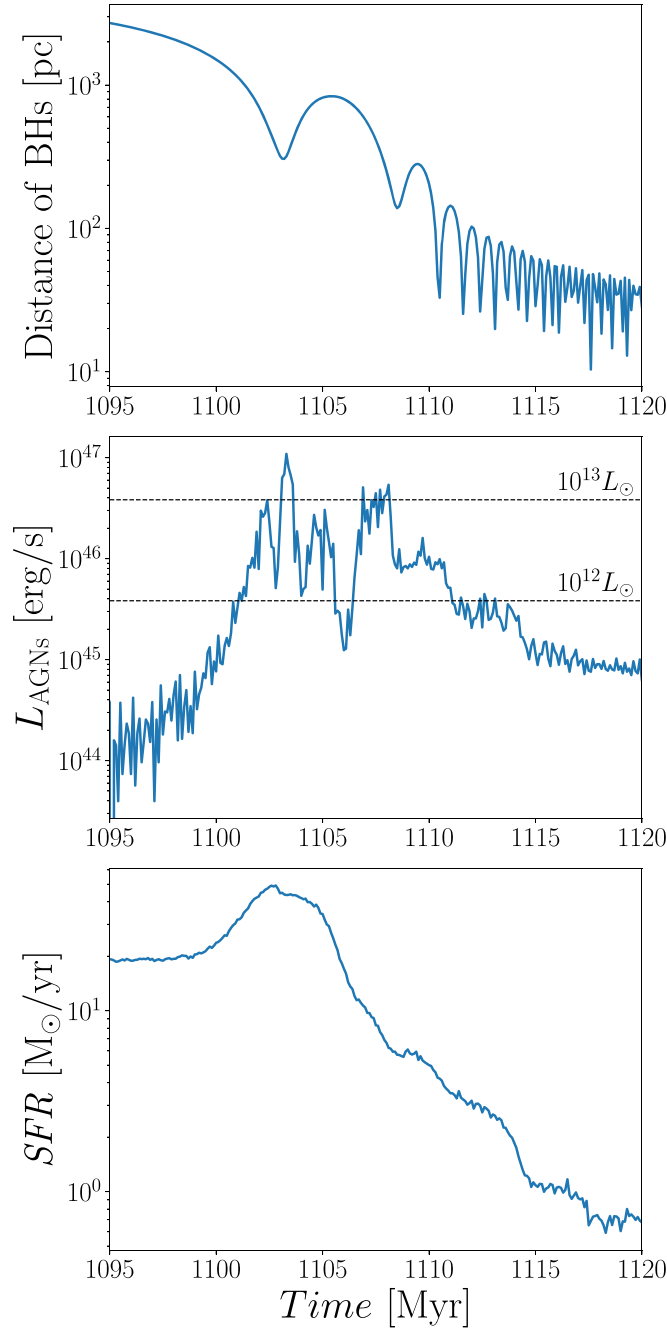

---

[10] We confirmed that the AGN luminosity is not affected when the cooling is stopped for 100 steps.

Figure 3. The time evolution of the distance between the two BHs (top panel), total bolometric luminosity $L_{AGNs} = 0.1 \times \dot{M}_{gas}c^2$ of the two AGNs (middle panel), and star formation rate (SFR) (bottom panel).

Figure 4. SEDs obtained using `RADMC-3D`. The redshift of the model was assumed to be $z = 2.0$. Solid, dashed, and dotted lines represent PL DOGs, bump DOGs, and non-DOGs respectively. Following Narayanan et al. (2010), the bump DOGs and PL DOGs are classified by their intensities at 3.6, 4.5, and 7.9 μm: $S_{3.6} < S_{4.5}$ and $S_{4.5} > S_{7.9}$ for bump DOGs and $S_{3.6} < S_{4.5} < S_{7.9}$ for PL DOGs. Top panel: time evolution of the SED at $\theta = 0°$. As the mass accretion rate increases, the SED becomes brighter in the mid-infrared. Bottom panel: comparison of the SEDs observed from $\theta = 0°$, 30°, 60°, 75°, and 90° at 1107.0 Myr. The SED for $\theta > 60°$ becomes fainter in the mid-infrared. Note that the SEDs in the near-infrared are not sensitive for the viewing angles. This is because of the vertical distribution of the stars and gas. See Figure 11 in Appendix A.

$N_{spec} = 10^5$. We used the default starting value of the random seed for the Monte Carlo simulation (-17933201). We have confirmed that the SEDs do not change significantly even if all three photon numbers are increased by a factor of 5.

3. Results

3.1. Mass Accretion to Black Holes

Figure 2 shows the gas density and temperature distributions from top to bottom $t = 1103.3$, 1107.0, and 1115.0 Myr. The first column from the left represents the gas density projected onto the x–y plane over 8×8 kpc^2, the evolution of the tidal tail due to collisions between the galactic cores. The second and third columns from the left also represent the gas density projected on the x–y plane and x–z plane over 800×800 pc^2, respectively. From 1103.3 to 1115.0 Myr, the decrease in density and increase in scale height of the gas disk can be observed. The rightmost column is the gas temperature projected onto the x–z plane over 800×800 pc^2. Local heating by supernova feedback can be confirmed. Although isotropic

from Weingartner & Draine (2001) ($R_v = 3.1$). This model includes silicate, graphite, and neutral and ionized PAHs. Opacity curves were obtained from Laor & Draine (1993).[11] The mass ratio of graphite to silicate was assumed to be $M_{gra}/M_{sil} = 1.0$.

In `RADMC-3D`, we must specify three types of photon numbers (N_{therm}, N_{scat}, and N_{spec}), where N_{therm} is used to determine the temperature distribution of the dust, N_{scat} is used to calculate the scattered light when calculating the intensity distribution, and N_{spec} is used to obtain the flux density. In this study, we assume that $N_{therm} = 10^6$, $N_{scat} = 10^6$, and

---

[11] Data available at ftp.astro.princeton.edu/draine/dust/diel/.

AGN feedback is implemented, we can observe a mass outflow driven by the AGN feedback in the z-direction from the gas temperature distribution at $t = 1107$ and 1115 Myr.

Figure 3 shows the BH–BH separation, total AGN luminosity, and star formation rate (SFR) of the system, as a function of time. As shown in the top panel of Figure 3, the distance between the two BHs gradually approaches each other while oscillating. The total bolometric luminosity $L_{AGNs} = 0.1 \times \dot{M}_{gas}c^2$ of the two AGNs reached a maximum of 1.09×10^{47} erg s^{-1} at $t = 1103.3$ Myr (middle panel of Figure 3). In this active phase, high-density regions ($n_H > 10^{3.5}$ cm^{-3}) were formed by the interactions between the two systems (see Figure 2). At 1102.8 Myr, the SFR reaches a maximum of 49 $M_\odot$ yr^{-1} (bottom panel of Figure 3). We found that L_{AGNs} exceeds 3.828×10^{46} erg s^{-1} (i.e., 10^{13} $L_\odot$) at approximately 1103 Myr. After $t = 1110$ Myr, L_{AGNs} decreased monotonically. After 1115 Myr, the two systems became relaxed, and the AGN luminosity decreased to less than 10^{46} erg s^{-1}. The gas in the disks is lost because of star formation, thermal AGN feedback, and angular momentum transportation in the active phase, and the average density of the disks is less than 10^3 cm^{-3} in the relaxed phase. In the following analysis, because we are interested in the formation and evolution of a DOG, we focus on the phase with relatively high total luminosity (i.e., t $\simeq$ 1100–1110 Myr) during which a large amount of gas remains around the AGN.

3.2. Infrared Spectrum

Figure 4 shows how the SED of the merger system depends on time and viewing angle θ for the observer. We perform pseudo-observations assuming that the model is at $z = 2.0$, because the population density of DOGs peaks around $z \sim 2$ (Dey et al. 2008). Here, we distinguish the SEDs obtained at different times and viewing angles using the DOGs criteria (i.e., $F_{24\mu m}/F_R \geqslant 982$ and $F_{24\mu m} \geqslant 0.3$ mJy). In addition, as in Narayanan et al. (2010), we classify bump DOGs and PL DOGs by their intensities at 3.6, 4.5, and 7.9 μm because bump DOGs have a peak around 4.8 μm in the observed frame ($z \sim 2$) (see the caption of Figure 4 for details). From the upper panel of Figure 4, we can see that the SED changes significantly from 1102.0 Myr to 1103.3 Myr. Between 1102.0 Myr–1103.3 Myr, the system becomes about 10 times brighter in the infrared (8–1000 μm). This corresponds to the change in the total AGN luminosity from 7.91×10^{45} erg s^{-1} to 1.09×10^{47} erg s^{-1} over 1.3 Myr (middle panel of Figure 3). This rapid change in luminosity can be expected from the dynamical timescales in the merger system. The middle panel of Figure 3 shows that the total AGN luminosity varies on a timescale of $\sim$0.1 Myr. This corresponds to the dynamical timescale of the nuclear region. The Kepler time period (i.e., $T = \sqrt{4\pi^2 r^3/GM_{BH}}$) at $r = 4.0$ pc from the SMBH with $M_{BH} = 10^8$ $M_\odot$ is about 0.075 Myr. The infrared luminosity increase was caused by the emission from hot dust near two AGNs. In other words, the infrared brightness of the merger system depends on the activity of the AGNs. Toba et al. (2017b) also reported a correlation between infrared luminosity and AGN activity for IR-bright DOGs.

From the bottom panel of Figure 4, we can see that the brightness in the infrared region decreases significantly as the viewing angle increases. This is because the radiation from hot dust in the vicinity of the AGNs is more severely attenuated by the material near the disk plane when the observer is closer to edge on. Note that all SEDs shown in this panel were obtained

Figure 5. Intensity distribution at 24 μm in the observed frame ($z = 2.0$) at $t = 1107.0$ Myr. Top panel: $\theta = 0°$. Bottom panel: $\theta = 75°$.

at the same time stamp; therefore, the material distribution and covering factor around the AGNs are the same for the SEDs, and only the viewing angle is changed. When the viewing angle is larger than 75°, the AGNs appear to be faint in the infrared because the dust thermal emission is self-shielded by the foreground cold dust, and consequently, the system no longer satisfies the DOGs criteria. The effect of the viewing angle depends on the wavelength in the infrared. For example, the dependence in the near-infrared region is smaller than that in the mid-infrared. This is because the optical to near-IR in the observed frame is dominated by stars whose scale height is much larger than that of the cold gas/dust that obscures the nucleus (see Appendix A). Figures 5 compares the maps of the 24 μm intensity S_{24} (Jy pixel^{-1}) at 1107.0 Myr for $\theta = 0°$ and
Figure 6. Comparison of the time evolutions of $F_{24\mu m}/F_R$ and $F_{24\mu m}$ in different viewing directions. From top to bottom, $\theta = 0°$, $60°$, and $75°$. The plus signs (+) denote points that do not satisfy the DOG criteria. Squares ($\square$) denote bump DOGs, and triangles ($\triangle$) denote the PL DOGs. The redshift of the model was assumed to be $z = 2.0$. The blue and red dotted lines show the DOG criteria of $F_{24\mu m}/F_R = 982$ and $F_{24\mu m} = 0.3$ mJy, respectively.
Figure 7. Infrared (8–1000 μm) luminosity of AGN origin vs. $F_{24\mu m}$ for $\theta = 0°$, $30°$, $60°$, and $90°$ during 1100–1115 Myr. $L_{IR}(AGN)$ does not include the contributions from stars. Plus signs denote time stamps that do not satisfy the DOG criteria. Squares denote bump DOGs, and triangles denote the PL DOGs. $L_{IR}(AGN)$ is positively correlated with $F_{24\mu m}$.

$75°$. At $\theta = 0°$, it was confirmed that the mid-IR emission was dominated by the vicinity of the AGNs ($r < 10$ pc). In contrast, at $\theta = 75°$, the radiation from the warm dust in the polar direction was dominant.

Figure 6 shows the time evolution of $F_{24\mu m}/F_R$ and $F_{24\mu m}$ at different viewing angles. Hereafter, we use T_{tot} to denote the total duration of all periods in which the system is categorized as a DOG (i.e., $F_{24\mu m}/F_R \geqslant 982$, $F_{24\mu m} \geqslant 0.3$ mJy). When observed face on ($\theta = 0°$), T_{tot} is about 4.1 Myr, but for

$\theta = 60°$, it is about 1.3 Myr. Furthermore, from $\theta = 75°$, it becomes even shorter, that is, T_{tot} is approximately 0.1 Myr. This is mainly because $F_{24\mu m}$ becomes faint at large θ, as shown in Figure 4 and fails to meet the DOGs' flux threshold. These results suggest that the lifetime of a DOG depends on the amount of cold dust ($T_{dust} < 100$ K) between the system and the observer as well as the timescale of mass accretion, that is, how long hot dust ($T_{dust} < 300$ K) is sustained by the AGN feedback (see above). The amount of cold dust in the line of sight and the contribution from the hot dust near AGNs are the key factors that determine whether a system is apparently classified as a DOG.

In the top panel ($\theta = 0°$) of Figure 6, it is noteworthy that in the early part of the DOG phase, the merger system is observed more frequently as a bump DOG than a PL DOG, while in the late part it is vice versa. In other words, the system is found to evolve from a bump DOG to a PL DOG. Although this result is similar to the evolution in the mid-IR SEDs from bump like to PL like discovered by Narayanan et al. (2010), the detailed time evolution and transition between the phases were not clear owing to the limited time resolution in their simulations. Our results show the evolution from bump DOGs to PL DOGs with sufficient time resolution. We have confirmed the transition from bump DOGs to PL DOGs with better time resolution (10 Myr versus 0.1 Myr). In the early DOG phase, the emission from hot dust ($T_{dust} > 300$ K) hardly contributed to the flux at 8 μm in the observed frame because the AGN was deeply buried (see Figure 2), resulting in the dominance of bump DOGs. However, in the late DOG phase, PL DOGs are dominant because the gas in the disks is lost due to star formation, thermal AGN feedback, and angular momentum transportation. In other words, the evolution from bump DOGs to PL DOGs is
Figure 8. Map of column density projected to the x–y plane at $t = 1103.3$ Myr (top panel) and 1107.0 Myr (bottom panel).

Figure 9. Top panel: $N_{H,24\mu m}$ vs. L_{IR}(8–1000 μm). Bottom panel: $N_H(8 \times 8 \text{ pc}^2)$ vs. L_{IR}(8–1000 μm) We assumed $z = 2.0$, and the plots were observed from $\theta = 0°$. The color bar represents the Eddington ratio. The plus signs do not satisfy the DOG criteria. Squares indicate bump DOGs and triangles indicate PL DOGs.

affected by AGN feedback. We confirmed that if the AGN feedback efficiency is increased from $\eta_{AGN} = 0.2\%$ in the fiducial model to 0.8%, the lifetime of the bump DOG phase becomes shorter, although the evolution from bump DOGs to PL DOGs in our model does not change (see Appendix B).[12] In addition, for $\theta = 60°$ (middle panel of Figure 6), PL DOGs do not frequently appear even in the late DOG phase. In summary, PL DOGs tend to be identified when observed face on in the late DOG phase in our model.

3.3. Energy Source for Merger-driven DOGs

PL DOGs have often been considered AGN-dominated sources in the infrared. One indirect piece of evidence for this interpretation is a positive correlation between the PL DOG population ratio and $F_{24\mu m}$ (Dey et al. 2008; Melbourne et al. 2012; Toba et al. 2015). To confirm the origin of PL and bump DOGs, we plotted the infrared luminosity arising from AGNs L_{IR}(AGN) versus $F_{24\mu m}$ in Figure 7. L_{IR}(AGN) is calculated by

running RADMC-3D without stellar radiation and integrating the resultant spectrum over 8–1000 μm. Clearly, $F_{24\mu m}$ positively correlates with L_{IR}(AGN), implying that the mid-infrared brightness represents the contribution from the AGNs in DOGs. The correlation coefficients for PL and bump DOGs were approximately 0.927 and 0.921, respectively. Thus, in our model, both PL and bump DOGs are strongly affected by AGN luminosity in the mid-IR. However, at the same AGN luminosity, the $F_{24\mu m}$ of PL DOGs tends to be brighter than that of the bump DOGs. The differences between PL and bump DOGs are discussed in Section 4.1.

4. Discussion

4.1. Evolution of Merger-driven DOGs

In Section 3, we show that the merger system in our model has the same observational properties as DOGs, albeit depending on the viewing angle. Contrary to intuition, the
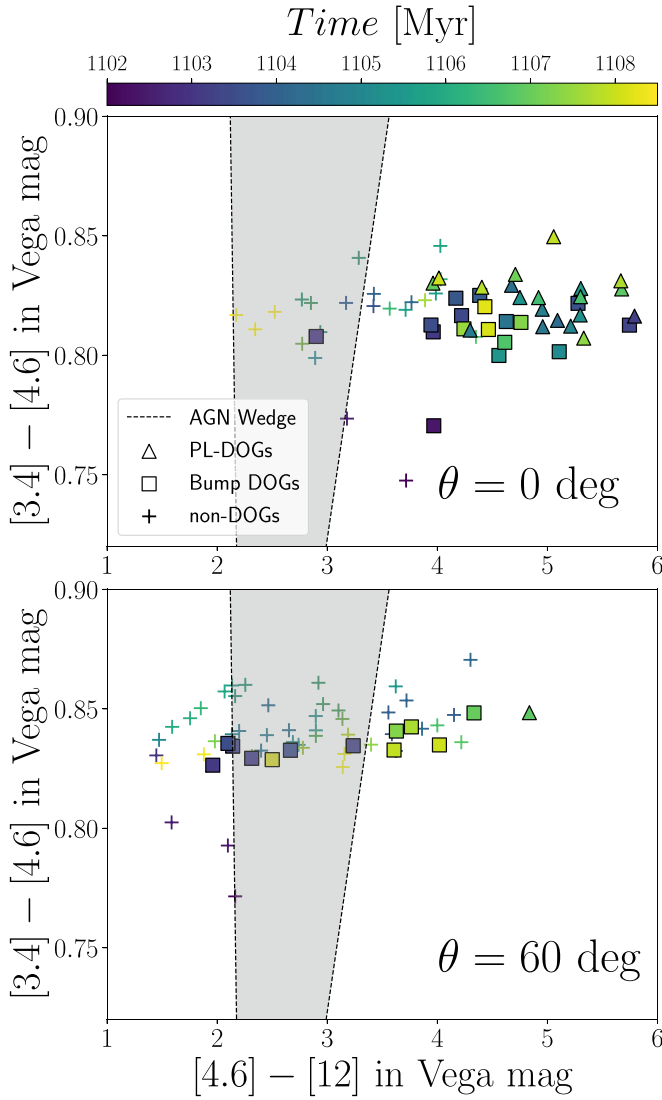

---

[12] Note that no bump DOG phase is observed for $\eta_{AGN} = 2.0\%$.

Figure 10. Time evolution of the system in the two-color diagram ($z = 2.0$). The AGN wedge is represented in gray (Mateos et al. 2012). The plus signs do not satisfy the DOGs criteria. The meanings of the plus, square, and triangle symbols are the same as in Figure 9. Top panel: $\theta = 0°$, bottom panel: $\theta = 60°$.

merger system is more likely to be observed as DOGs based on their color and IR flux if it is closer to face on. This is because if the system is close to edge on, the hot dust around the AGNs, which is responsible for producing a sufficiently high IR flux, is self-shielded by the foreground cold and dense gas, which is concentrated near the disk plane. As described in Section 3.2, the top panel of Figure 5 shows the intensity distribution of $I_{24\mu m}$ in the observed frame when observed face-on ($\theta = 0°$) at 1107.0 Myr. The top panel of Figure 5 also shows that a bright core in the mid-infrared region is associated with each SMBH. It should be noted that the current observations cannot resolve the structures of DOGs at $z > 1$ on a subkiloparsec scale. Therefore, we currently have no observational information on the spatial structure of the DOGs' central region. We discuss this based on the results of our numerical simulation.

Figure 8 shows the gas column density projected onto the x–y plane at $t = 1103.3$ Myr and 1107.0 Myr. At $t = 1103.3$ Myr, we confirmed that the AGNs were buried in gas with a column density of 5×10^{23} cm^{-2} or greater. At that time, a cavity of 10 pc was formed by feedback from each AGN. However, at

$t = 1107.0$ Myr, the column density averaged at $r < 100$ pc is lower than 5×10^{23} cm^{-2} and AGN feedback cavities are seen more prominently.

The top panel of Figure 9 shows the time evolution of the column density when observed face-on. Here, the 24 μm intensity weighted mean column density $N_{H,24\mu m}$ is defined as

$$N_{H,24\mu m} = \frac{\iint N_H(x, y)\, S_{24\mu m}(x, y)\, dx\, dy}{\iint S_{24\mu m}(x, y)\, dx\, dy}. \quad (1)$$

We obtain the $S_{24\mu m}$ [Jy pixel^{-1}] distribution using RADMC-3D (e.g., Figure 5). The top panel of Figure 9 shows that the column density varied by an order of magnitude between 1101.0 Myr and 1103.3 Myr. During this period, the AGNs became buried with the supplied gas, and the Eddington ratio also increased by more than one order of magnitude. From 1103 Myr to 1104 Myr, the AGNs are deeply buried and the system is observed as a bump DOG (see Figure 9). Subsequently, the gas near the SMBH is blown out by AGN feedback, and $N_{H,24\mu m}$ and L_{IR} decrease. These results refine the bump-to-PL DOG evolution inferred from Figure 6 in Section 3.2. As a result, the system was observed as a PL DOG from 1104 Myr to 1108 Myr.

We also confirmed the evolution of the central column densities 8 pc from the AGN. The bottom panel of Figure 9 shows the evolution of the central column density, which is evaluated in the 8×8 pc^2 box centered on the SMBH, and the infrared luminosity. The column densities were averaged for the two SMBHs. We note that the simulated N_H and Eddington ratio explains well the distribution of the eROSITA-detected obscured AGNs (Toba et al. 2021). We can also confirm that there are two populations: PL DOGs with $N_H \sim 10^{23}$ cm^{-2} and bump DOGs with $N_H \sim 5 \times 10^{23}$ cm^{-2}. This difference occurs because the gas around the nucleus is consumed by the star formation and mass accretion to the nucleus.

4.2. Mid-infrared Color Selection for Merger-driven DOGs

Most luminous infrared galaxies are in the phase of advanced mergers and are powered by a mixture of circumnuclear starburst and AGNs (Sanders & Mirabel 1996). However, it is not straightforward to quantify the contribution of starburst and AGNs to their SEDs observationally. For example, in our case, both the star formation rate and mass accretion rate increased when the two galaxies approached each other (see Figure 3).

It is known that mid-infrared color selection is helpful for identifying AGNs (Jarrett et al. 2011; Mateos et al. 2012). This is because the dust in AGNs can be heated up to the sublimation temperature ($\leqslant$1500 K) by the intense UV radiation from the AGN. Thermal re-emission from the dust causes a power-law spectrum in the infrared range (3–30 μm); therefore, the difference in their colors can be used to infer the contribution of the AGNs.

Blecha et al. (2018) proposed a new color selection scheme for AGNs using WISE for nearby ULIRGs. They also showed the evolution of nearby ULIRGs on the WISE two-color diagram. However, DOGs are generally observed at high redshifts ($z > 1$) (Dey et al. 2008). The classification on the WISE two-color diagram ($[3.4] - [4.6] > 0.5$, $[4.6] - [12] > 2.2$, and $[3.4] - [4.6] > 2.0 \times [4.6] - [12] - 8.9$) of the nearby ULIRGs ($z < 1$) cannot be directly applied to DOGs.

In Figure 10, we plot evolutional tracks of DOGs ($z = 2.0$) on the WISE two-color diagram. This shows that DOGs are distributed both inside and outside the AGN wedge (Mateos et al. 2012). Therefore, these results suggest that AGN wedge on the WISE two-color diagram does not necessarily correspond to merger-driven DOGs. The mid-infrared color varies significantly with θ, and PL DOGs tend to be redder than bump DOGs in [4.6] – [12]. In addition, for $\theta = 60°$, [4.6] – [12] tends to be bluer than for $\theta = 0°$. [4.6] – [12] is sensitive to radiation from the AGN, whereas [3.4] – [4.6] shows no significant change during the DOG phase. Our results indicate that DOG color selection is challenging.

5. Summary and Conclusions

We simulated the final phase of galaxy collisions' resolved dust-torus scale (several tens pc) using the N-body/SPH code ASURA (Saitoh et al. 2008, 2009; Saitoh & Makino 2013) to explore the origin of DOGs. Snapshots obtained from the N-body/SPH simulation were used as inputs to the radiation transport simulation code RADMC-3D (Dullemond et al. 2012) to investigate the evolution of the SED including its dependence on the viewing angle. The goal of this simulation is to determine the power source of merger-driven DOGs and to clarify the relationship between PL DOGs and bump DOGs. The main results are as follows:

1. In the final phase of galaxy mergers, we have found snapshots that satisfy the spectral characteristics of bump DOGs and PL DOGs. (See Sections 3.2 and 4.2.)
2. The SED changes significantly over a few Myrs corresponding to the timescale of mass accretion to $r < 4$ pc. (See Section 3.2.)
3. The lifetime of DOGs changes depending on the viewing angles because the contribution of AGNs is attenuated by the high column density of the dusty gas as the viewing angle increases (i.e., closer to edge on). (See Section 3.2.)
4. For merger-driven DOGs, we have confirmed that bump DOGs evolve to PL DOGs. This result is consistent with the scenario proposed by Dey & Ndwfs/MIPS Collaboration (2009). Narayanan et al. (2010) also reported a similar transition in the mid-IR SEDs. We have confirmed the transition of DOG types with a better time resolution of 0.1 Myr. Furthermore, the transition was

observed even when the AGN feedback efficiency η_{AGN} was increased from 0.2% to 0.8%. We note that as η_{AGN} is increased, the lifetime of bump DOGs in the early DOG phase will be shorter, and the bump DOG phase is no longer observed for $\eta_{AGN} = 2.0\%$. (See Section 3.2 and Appendix B.)

As a final remark, one should note that the numerical treatment of triggering AGNs during the gas-rich merger of our simulations is still idealized, in the sense that we do not correctly solve detailed physical processes within 4 pc of the SMBH. The current model of the fueling process for the AGNs and the feedback from the AGNs is simplified. We are planning to perform 3D hydrodynamic simulations inside the 4 pc near the SMBH using the mass accretion rate in this study as a boundary condition to resolve the structure within 4 pc from the SMBH in the late stages of a galactic collision. We believe that this will allow us to better assess the structure of AGNs in the late stages of galactic collisions.

Appendix A
Near-infrared Images and SEDs

The SEDs shown in Figure 4 (bottom) do not exhibit significant changes in the near-IR at $t = 1107.0$ Myr. This is because radiation from the stellar system is dominant in the near-infrared, and AGNs are buried in the foreground cold dust and gas. Figure 11 shows that the shorter the wavelength, the more important the radiation from the high-scale-height regions.

Figure 11. Intensity distribution in the optical to mid-infrared for $\theta = 90°$ at $t = 1107.0$ Myr.

Appendix B
Higher AGN Feedback Efficiency

We have confirmed how higher AGN feedback efficiency (η_{AGN}) affects the evolution of DOGs. Figure 12 compares the time evolution of $F_{24\mu m}/F_R$ and $F_{24\mu m}$ between $\eta_{AGN} = 0.8\%$ and 2.0%. The evolution from bump DOGs to PL DOGs was confirmed for the AGN feedback efficiency of 0.8% as well as for the fiducial model ($\eta_{AGN} = 0.2\%$). However, we note that

the lifetime of bump DOGs for $\eta_{AGN} = 0.8\%$ is shorter than that of the fiducial model (see Figure 6), and no bump DOG phase is observed for $\eta_{AGN} = 2.0\%$. In other words, as AGN feedback efficiency increases, PL DOGs are observed more frequently in the early DOG phase. This is probably because the more powerful AGN feedback blows away the cold dust on the line of sight, and thereby, it becomes brighter in the near-infrared.

Figure 12. DOG-type evolution for $\theta = 0°$ with varying AGN feedback efficiency (η_{AGN}). In the top panel, η_{AGN} is 0.8%; in the bottom panel, η_{AGN} is 2.0%.
